An Application for Controlling a Wireless Sensor Network Using a Smartphone

by Costas Zarifis

The use of smartphone devices over the past years seems to follow a growing trend. This great acceptance along with the endless possibilities that go hand to hand with having a mini computer at all times within reach, can explain this vast interest shown by solo developers and major companies in the mobile industry. As a result, many innovative applications roll out daily to the various online stores, making the lives of the smartphone users a lot better. This thesis describes the design and implementation of a mobile app, a Web Service and a TinyOS application, that bind together allowing the user to execute a variety of queries on a sensor network from any place in the world.

Until now, the user of a sensor network was usually constrained to be in the same room or area in which the network was installed, in order to execute a query and receive the measurements retrieved by the sensors or to detect outlier measurements from motes. Although nowadays there are various programs that enable users to operate a sensor network, they do not effectively resolve some issues that arise. Many of these programs do in fact have a graphical user interface (GUI) that allows the users to operate on it, but it is usually somewhat outdated and abstract. As a result the user can easily get confused while using it. Additionally, since they have not received any major updates recently, they usually cannot run on modern operating systems and more importantly, they can only run on conventional computers and not on mobile devices.

The user of the mobile application developed as a part of this Thesis on the other hand, can operate a Wireless Sensor Network (WSN) without the aforementioned limitations. The user-interface of this app is simple and easy to use, following the trends set by Google and other major companies. Additionally, since this is a mobile application, the user can use it while on the go, without geographical restrictions. He could be in the same room where the sensors are installed, or in an entirely different continent and still be able to use the sensor network, as long as there is internet access.

Mobile applications certainly have many advantages over applications that are intended to run on desktops or laptops but they also come with some restrictions. The limited battery life that the majority of these devices have, is without a doubt the most important concern for a developer. Big screens with high resolution may be easier to view and operate on (not to mention impressive), considering the fact that almost every single smartphone produced today comes with a touch screen, but it has a big impact on the battery life. The same applies to radio usage. Wi-Fi and 3G-4G networks can drain the battery within a few minutes of heavy traffic. The mobile app developer should also keep in mind that even if the majority of these device have a respectable processing power for a mobile device, it really is no match for the processing power of conventional desktops and laptops. Additionally, the fact that these smartphones support multitasking can affect even more the already limited processing power. What multitasking means is that other processes are executed simultaneously. As a result other processes may use the same resources our application uses. It is therefore important to develop applications that do not overuse the provided resources, as this may cause problems to other applications running on the background.

More or less the same principles apply when developing the applications run on the sensor network. While the Operating System used by the motes is fairly lightweight and the CPU as the rest of the hardware configuration does not seem to be very power consuming, it is important for the developer to keep in mind that he should find ways to keep radio and CPU usage to the minimum. Furthermore, these devices have a limited flash memory which means that the produced executable file has to be relatively small as well.

Last but not least, in order for the before-mentioned parts to tie together, a web service had to be implemented. The client, which in this case is the mobile application, interacts with the mote network using internet access. In order for this to be possible the client should first interact with a web service that "listens to" a specific public internet address, which in turn interacts with the mote network. Basically, the role of the web service is to disseminate messages between the mobile app and the sensor network and to keep track of the activities that take place.

Acknowledgements

First of all, I would like to thank my Thesis supervisor Prof. Antonios Deligiannakis for his continuous inspiration, support, and trust during our cooperation. I would also like to thank the members of the examination committee Prof. Aggelos Bletsas and Prof. Minos Garofalakis.

Furthermore, I would like to thank from the bottom of my heart Antonios Igglezakis, who did an amazing work on his outlier detection application, which he let me integrate into my Thesis. His assistance was more than helpful and his patience is certainly one of his most valuable virtues.

In addition, I want to thank my friends for their moral support and their belief in me for the past years, and of course for being there for me during the times I needed them the most. I'm really honored to have met you guys and I wish you nothing but the best!

Last but not least, I can't find the words to describe the help, support and never-ending love I receive daily from my beloved family, not to mention their patience and understanding over the past few years.

List of Figures

Chapter 1

Introduction

1.1 Mobile Industry and Mobile Software Development

The use of smartphone devices over the past years seem to follow a growing trend. In 2011 there where 835 million smartphone users, which corresponds to 40% of total mobile subscribers, with that number being expected to double by 2015. In addition, it should be noted that research from Morgan Stanley states that by 2015, the total number of mobile users browsing Internet will be more than that of the desktop.

The role of applications combined with the flexibility they offer, are the major factors behind the popularity of smartphone usage. The time spent on applications compared to the time spent on websites has grown from 73% (2011) to 81% (present). The number of new subscriptions to Android and iOS systems, which at the moment lead the smartphone market share, in the first half of this year had already crossed 84 million compared to the total number of 2011 year subscriptions which was 38 million. The average number of applications per smartphone has increased from 32% to 41%. Moreover, the percentage of app downloads in Android and iOS operating system phones has grown from 74% to 88%. All these statistics indicate that mobile industry is without question on a raise.

These figures also show that mobile development offers opportunities for profit not only to software companies but to solo developers as well. Innovative software can easily be built and help users in their personal and professional lives. In addition, due to the fact that more and more developers get involved into mobile development, it is not unusual for companies and simple users to hire experienced solo developers to build customized applications that satisfy their needs completely.

Android is, at the moment, one of the most popular mobile platforms, with hundreds of millions of mobile devices in more than 190 countries around the world, with daily activations surged from a million Android devices back in June of 2012 to today's number of 1.3 million. additionally, Android is a Linux-based operating system designed primarily for touchscreen mobile devices. It is developed by Google in conjunction with the Open Handset Alliance, which is a consortium of 86 hardware, software, and telecommunication companies devoted to advancing open standards for mobile devices.

In addition, Google has released the Android code as open-source, under the Apache License. Open-source software is known to act as a magnetic pole to developers and surely Android is no exception to that. A great number of developers are actively involved in Android development not only by building simple applications but in other ways as well. Custom ROMs, which are aftermarket firmware distributions, are too many to count. The importance of this factor for a buyer, when deciding what mobile device satisfies him the most, is crucial. This is explained by the fact that mobile device manufacturers usually stop offering software updates to older devices even if the hardware can support them, mainly due to financial reasons. This is where custom ROMs step in, as the amount of money a buyer invests into an Android device will not lose its value after a couple of months, because these custom ROMs will keep the software of the device up to date. All in all, having followed for a long time the developments on mobile industry, it seemed that choosing to build the client as an Android application was the way to go.

1.2 Sensor Network and TinyOS

A wireless sensor network (WSN) consists of spatially distributed autonomous sensors that monitor physical or environmental conditions, such as temperature, sound, pressure and so forth while they cooperatively pass their data wirelessly through the network to the base station. The development of wireless sensor networks was motivated by military applications such as battlefield surveillance. Today such networks are used in many industrial and consumer applications, such as in the industrial process of monitoring and control, machine health monitoring, and so forth.

The sensor nodes used in this application use TinyOS as their operating system. TinyOS is a free open source, BSD-licensed, component-based operating system, designed for low-power wireless devices. TinyOS is written in nesC(network embedded systems C) programming language. There is a worldwide community from academia and industry that uses, develops and support TinyOS and its associated tools. This operating system is less common in the embedded world of sensing and control. In the area of the

embedded systems, applications are usually bound to a specific hardware. This is preferred due to the very limited hardware resources and the degree of specialization of the applications.

On the other hand, WSNs sensors are embedded but general-purpose that can support a variety of applications and at the same time they manage to support heterogeneous hardware components. In addition, wireless networking requires greater concurrent processing than wired protocols. As a result while a WSN node is carrying out its normal data acquisition and processing steps, it also needs to service protocol events and packet transfers that arise asynchronously from the network. However, hardware resources remain diverse and constrained, especially in terms of memory and power.

TinyOS was designed specifically for WSNs. It introduces a structured event-driven execution model and a component-based software design that enhances robustness, and minimizes power consumption to the minimum. The components that can be used by this system, use well-defined interfaces to connect with each other. These interfaces resemble schematic wires that "glue" hardware components together.

However, besides all the above-mentioned positive facts about WSNs, TinyOS and nesC, developing an application intended to run on a real life sensor network is considered to be a fairly hard task. In fact, even the execution of an application and the interaction of the sensor network with a computer requires a good understanding of these technologies that surely is not found on the average PC user. Not to mention, that terminal is primarily used to interact with the network and surely not every user is familiar with it. Of course, there are clients that manage to interact with the sensors in a satisfying manner, but most of them have not received any major update in years. This has an impact not only on the graphical user interface (GUI) which feels outdated, but on the fact that they are not compatible with the later versions of OSs found on most modern PCs. All these facts combined with the mentioned raise of smartphone devices were the motivation of this thesis project.

1.3 Web Services

Web services caught the attention of the IT industry back in 1999 when a press conference was held in San Francisco by Microsoft. Microsoft Chairman Bill Gates, introduced the world to a new revolutionary concept called BizTalk which was later formalized under the name ".Net". As Bill Gates cited, web services are supposed to manage the interconnection issues between different types of software peaces together. In addition, these different software programs can be developed in completely different programming

languages and run on completely different hardware without causing any problems on their interconnectivity.

Since, in our case, the Android device had to be able to connect to the sensor network, without any proximity limitations to the area where the sensor network was installed, a web service had to be used. The primary concept of web services is that a client sends a request over HTTP (or any similar protocol) to an address in which the web service is hosted and "listens to". When the web service receives it, it sends a response back to the client with the requested data. The developer of the client does not have to be aware of what is happening in the server side, he only needs to make sure that the messages that are sent and received follow the rules that the provider of the service has set. On the other hand, the business logic that runs on the server side is completely up to the developer of the Web Service as long as the data returned to the client, again, follow the rules he set.

1.4 Thesis Contribution

The main object of this thesis was to find a way to assemble these three parts, the sensor network, the android application and the web service, in such manner that will let users use a sensor network without any prior knowledge to any of these fields. In order to achieve that goal, it was important to make sure that final user would not have to worry about technical issues since that user could be virtually anyone. Any user that just wants to keep track of the temperature, light or humidity levels of an area, which could be his house or his office, had to be able to do so without any technical concerns. Thus, the interface of the application had to successfully inform the user, providing him with the data he needs in a clean and minimalistic design, without demanding too much effort on his part. Of course since the target user of this system can be anyone with or without any prior technological knowledge we had to make sure that precautions had to be taken in order to avoid destructive use of the system.

It should be mentioned that this application works in the same way no matter what it measures. The fact that TinyOS is a component-based OS provides the option to use components that especially measure what the end user wants without any changes to the main code of the application with just a minor change on the wiring. That way, it is possible to satisfy the needs of a broader audience and use the system in a variety of situations since it is possible to receive any kind of measurement and not be limited to a specific one.

In order for someone to use this system a number of sensors running TinyOS have to be acquired. Right after the installation of the provided application on each and every one of them, they should be placed into the area on which they will operate. The base station of this network must be connected to a computer system with internet access. After acquiring a unique internet address and having initiated the service on the computer system, it is ready to accept incoming messages from the client. The client in this case, is the Android App. When the user creates an account with his personal details, through the application he can log in and start using the system.

When a user chooses the operation he wants, a request message is sent to the Web Service. Right after all checks take place in order to make sure that the sent message is valid, the Web Service sends a message with the chosen settings to the base station. From this moment the sensor network operates autonomously, configuring all the variables required to execute the right query with the selected settings and periodically sending messages back to the base station that are forwarded to the Web Service. When the web service receives a message from the sensor network, it instantly saves the data to a database and forwards them to the client. At this point the client is responsible of presenting the measurements in an easily comprehensive manner.

Chapter 2

Architecture

Since we have roughly described how the system works. It is time to analyze some of the architectures that had to be used in order to be able to implement this system.

2.1 Client-Server Model

The client-server model is a computing model that acts as a distributed system, partitioning tasks or workloads between the providers of a resource or service, called servers, and service requesters, called clients. Usually clients and servers run on different machines and communicate over a computer network, but it is possible for both clients and servers to reside in the same system, although this usually only occurs while developing and testing the service and the client.

A server machine is a host on which one or more server applications run sharing their resources with clients. The main job of a server is, as its name states, to serve requests sent from the clients by sending them back the requested content. Clients are therefore the ones that initiate the communication between them and the applications that reside on servers.

This model goes way back, at a time when servers were large-scale mainframe computers that occupied large rooms and were connected to simple terminals, but since then many things have changed. Through the years, personal computers started to evolve and replaced these terminals, but the processing of data continued to take place into the mainframes. With the improvement in computer technology, the processing demands started to split between personal computers and mainframes. This brings us to the present, where personal computers can still run as clients but they also possess enough processing power to process data on their own.

Today there are three kinds of clients:

- **Fat Client.** Is also known as rich client or thick client. This type of client is responsible for processing data by itself since it does not rely on a server for this but acts more autonomously. In addition, This client runs on a machine that is powerful enough to process the data and not just display them to the user, thus the requirements for the machines hosting this type of client are higher than the ones hosting the following clients.
- **Thin Client.** This type of client is only responsible for the graphical visualization of the data retrieved from a server. Since the data are received already processed by the server, these clients can run usually in low-end machines as the processing power is not usually an issue when displaying data.
- **Hybrid Client.** This client is a mixture of the previously mentioned types of clients. It relies on the server to retrieve the data but he processes them locally. The hardware requirements of this client vary depending on how heavy the data processing procedure is.

2.1.1 Two-Tier Architecture

Encapsulation is a design idea related to the existence of compartmentalization within a system. The main point is that the developer is not obligated to know exactly how a component is implemented in order to use it. The components resemble black boxes, which the developers can use and build their own applications without any knowledge of their implementation specifics. That way, as long as the interface between components does not change it does not really matter how the are implemented.

The only thing that surely remains constant, is that the term Two-Tier Architecture describes a software architecture model that consists of two parts, clients and servers. Clients connect to a server over a network and use the downloaded data to operate on. In earlier years, these clients connected to a file server and obtained entire files from its hard drive. As this architecture was used more and more the limitation of file sharing became obvious. The network traffic was too high for the amount of useful information acquired by the clients. This problem was resolved by using database servers instead of file servers. This way the server-side only transmits the useful data that the client needs thus decreasing the network traffic and allowing more clients to use the same resources.

Typically, both Structured Query Language (SQL) and Remote Procedure Calls (RPCs) were used to communicate between the client and server. The Two-Tier client-server

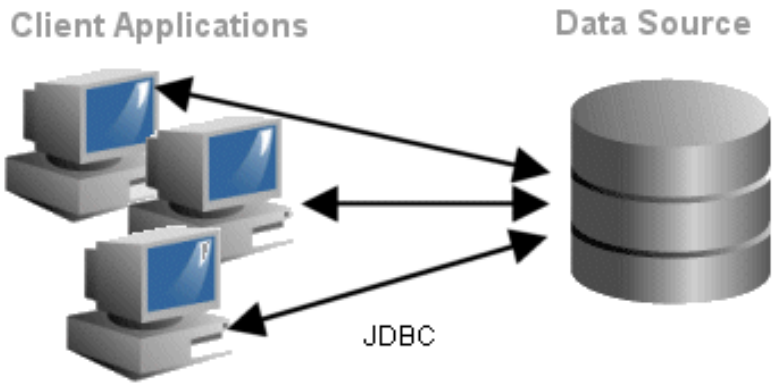

FIGURE 2.1: *Two-Tier Architecture.*

architecture was widely used and still is in some occasions. In this architecture, clients directly connect to the database server. The database server process might be hosted on the same machine where the the client runs (localhost) or on a remote machine. This architecture offered a good application developing speed, but as the number of clients raised along with the data that had to be transmitted, this architecture showed its weaknesses.

The disadvantages of having a client directly connected to a database are numerous. The most important ones are the following:

- **Security.** It is considered a bad idea to grant direct access into a database to anyone without an intermediate level of security.
- **Cache.** As the number of requests raise, the database has to continuously execute request queries on its tables. Instead, it would be a good idea to use some sort of cache when the results remain unchanged over time.
- **Scalability.** As the data get bigger it is sometime useful to use more than one data resources in parallel in order to achieve better load balance. This is extremely difficult since it requires changes on the client side that may not be possible in some cases to occur.
- **Encapsulation.** Sometimes changes have to take place on the database implementation. This will cause problems on the clients since the queries that are executed have to change and the only way to do that is by changing the (remote, at times) clients.
- **Portability.** Since a client program might be cross-platform, creating a data access layer into each platform's clients may be too hard compared to creating a

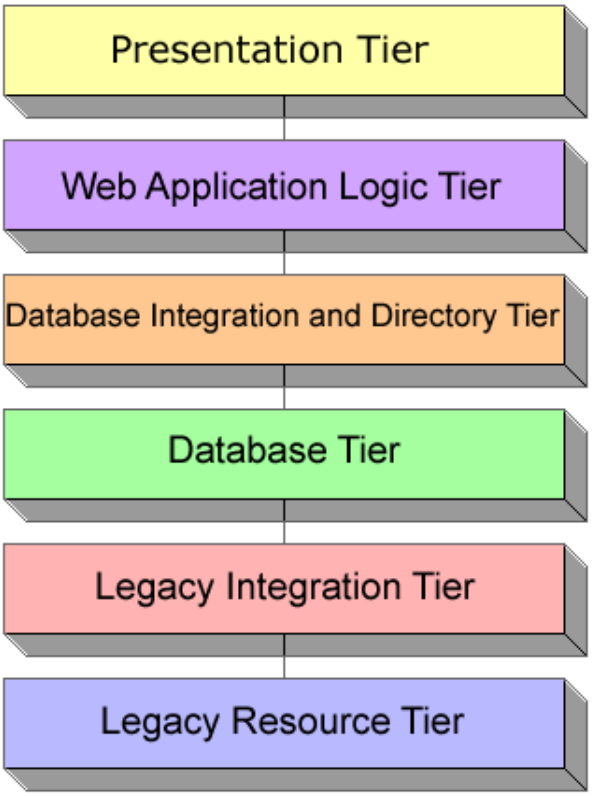

FIGURE 2.2: *Multitier Architecture.*

consumer layer that simply connects to a component used to feed the client with the same data without platform specific details.

- **Performance Tuning.** Since a content provider might allow third-party applications to connect and retrieve the data he provides, it is almost positive that the queries run on the database will not be the most optimal, since the third-party developers might not be aware of what kind of tuning has been performed to the DB.

The need for an intermediate level between the client and the database, that solves the above-mentioned issues, was obvious.

2.1.2 Multitier Architecture (N-Tier Architecture)

N-tier application architecture provides a model by which developers can create flexible and reusable applications. The segmentation of an application into tiers provides developers with the ability to implement or change a specific layer without having to modify the rest of the layers.

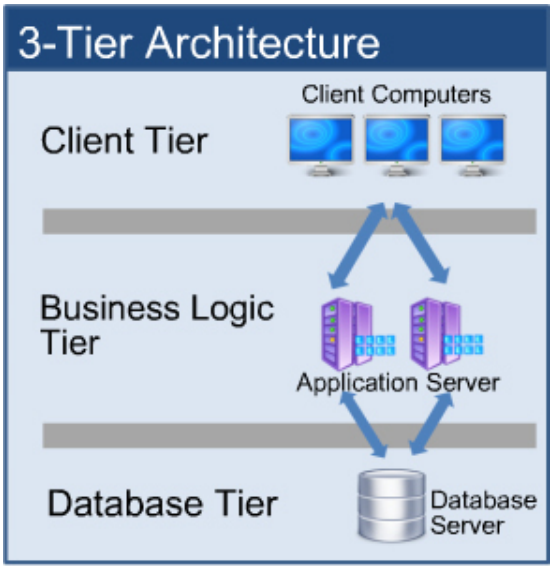

FIGURE 2.3: *Three-Tier Architecture.*

Three-tier architecture is the most used architecture. It typically consists of a presentation layer (client) which is responsible for the presentation of the data retrieved from the server, a data access layer which is responsible for accessing the data that the client has requested and an intermediate part that connects the two other layers in a secure way.

2.1.3 Error Handling

Since this model operates on a distributed environment, through a network there are many problems that may occur. Some of these problems are the following:

- The database might be down.
- The network may be unavailable.
- The client is trying to connect with the server in order to add existing data into a database.
- The client is trying to operate on data that require some kind of permission.

These were only some of the problems that may occur and that they should be handled in a secure and robust way. It is also important that the user has to be informed, in a comprehensive way, about what exactly goes wrong, when this happens.

2.2 Model View Controller (MVC)

Model View Controller is a design pattern invented by the Smalltalk programmer Trygve Reenskaug, and it has been used in a variety of frameworks, including the one used for building Android applications. The model consists of three parts:

- **The Model** which is responsible for managing the behavior of the application domain by responding to request that require the retrieval or modification of data.
- **The View** which is responsible for displaying information on the screen.
- **The Controller** which is responsible for the collection and interpretation of the users' actions, such as clicks, scrolls and so forth, and the execution of the appropriate code to serve them. Additionally, the Controller is responsible for the updates performed on both the model and the view in such a way that will give the users a feeling of reaction to their actions.

At this point, it should be mentioned that both the view and the controller depend on the model, but the model is independent from both the controller and the view. In many rich-client applications, view and controller are implemented as one object, however in most web applications there is a clear separation of the two since the usage of a universal client, which in this case is the browser, demands this approach.

The main advantage of this pattern is the ease of testing and the compartmentalization. When developing large-scale applications there are too many components connected with ways that it makes it too difficult to even test a simple function. Even worse, when an error occurs it is too difficult to locate the problematic component and solve the issue. This is why the MVC design pattern is so popular, because due to the clear separation of the components, the developer will know where to look for the problem if this occurs. In addition when there is a graphical user interface (GUI) it is even more time consuming to test the application, but since the developer can test the model separately from the view he can make sure that the model works without having to simulate every single use case.

2.3 Comparison Between Three-tier and MVC Architecture

After having analyzed both Three-tier and MVC architectures one can easily observe that they are quite similar. Both of these architectures exploit the compartmentalization of an application into components that connect with each other. But the main difference

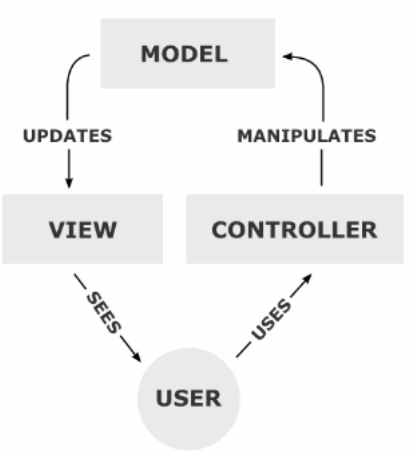

FIGURE 2.4: *ModelViewController.*

is that three-tier architecture is linear, as the client never ties directly to the database without using the intermediate layer, on the contrary the MVC architecture is triangular. the view sends updates to the controller, the controller updates the model, and the view gets updated directly from the model.

2.4 N-Tier Architecture in this Implementation

In the system created for this thesis implementation, there are four components that have to bind together, as it can easily be noticed by looking at figure 8.1. There is the Android application, the web service, the sensor network and the database. The Android application behaves as a client. The user interacts with the client in order to use the sensor network. The client interacts with the web service to control the sensor network and to perform actions such as signing up and logging in and out of our system. A certain level of abstraction has to be implemented, as the user should not be bothered with communication specifics and so on. He should just be aware of the important data and the state of the system.

The web service on the other hand acts as the connecting link between the client and the other components. It can be imagined as the middleman of the system. It exchanges messages with the client, the database and the sensor network in order to bind these components together. The web service should provide all the necessary information to the client (and indirectly to the user), while at the same time it ensures the security and the well-being of the system.

The sensor network also interacts with the web service. When a query has to be executed, a message is sent via the web service to the base-station. The base-station, which is the

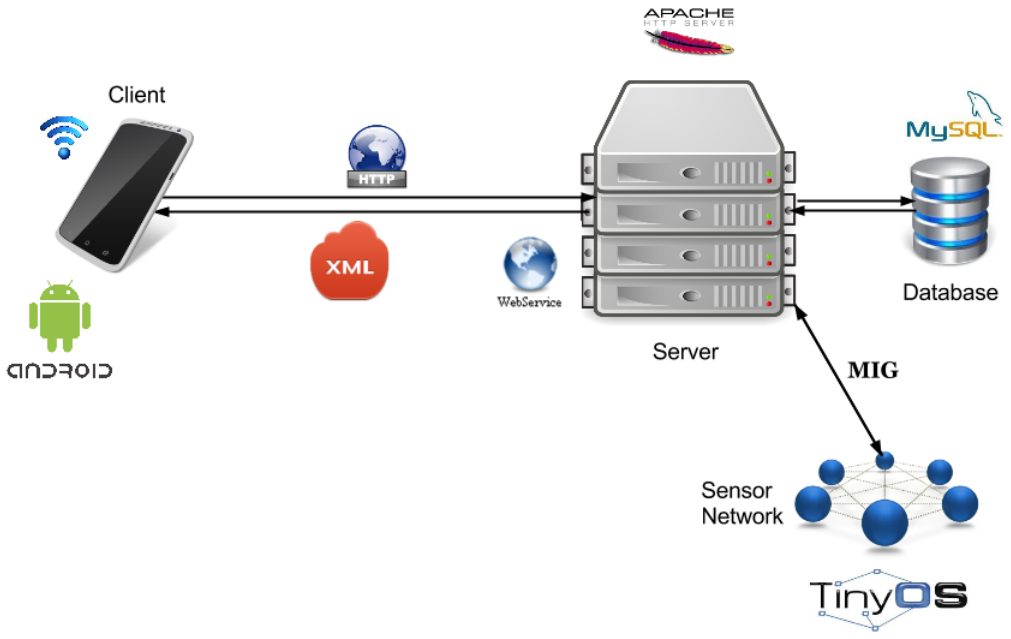

FIGURE 2.5: *Architecture of the Implemented System.*

only mote that has to be connected to the web service, receives this message, it decodes it and it transmits the useful data to the rest of the motes wirelessly. Right after every node has received this routing message, they are aware of the execution specifics and they begin the selected function. Every time, a message is sent to the base-station it is being forwarded and stored in the database. That way, users can access previously executed queries easily.

Finally, a database is used to store the received measurements of the sensor network. Apart from the measurements, the database keeps the user accounts, where information such as, the exact time when users signed up or logged into our system are stored, along with other elements such as avatar pictures and more. Additionally, since the web service is stateless, some tables are used to store some sort of "state" in order to avoid problems such as the simultaneous execution of a query on a single sensor network by more than one users.

To sum up, in order to implement the expected functionality, we had to create a 4-Tier system. The client in our case, is a mobile application, run on an Android device, the

FIGURE 2.6: *Eclipse - Popular IDE.*

TinyOS application clearly runs on the sensor motes, while the web service and the database are hosted on the same machine.

2.5 Integrated Development Environments (IDE)

An Integrated Development Environment is a PC application that provides to the developer all the tools necessary for a successful software development. Usually it consists of:

- **A source code editor.** Typically this is a text editor designed in a way that simplifies and speeds up the process of code writing. This is usually done by a number of functionalities such as syntax highlighting for a specific programming language, auto-complete, bracket matching and more.
- **A build automation tool.** This tool is used in order to let the developers focus on coding without having concerns about compiling, building and executing a program, since this is done with a single click from the UI of the IDE.
- **A debugger.** While coding some bugs are expected to occur. A debugger is used to make the developer's life, easier while spotting and resolving them. Basically, it provides tools that allow the developers to examine how the program is being executed allowing them to trace the problematic part which is responsible for crashes or unwanted behavior.

Today there is a variety of IDEs available. Some of them are bound to a specific programming language, while others are multi-language. In addition, some of these applications are free like Eclipse, NetBeans and Anjuta while others require a fee to download and use like Microsoft Visual Studio. It should be mentioned at this point, that there are alternative ways to implement an application, for example a developer can just use a simple editor and a terminal, and there are many reasons for a developer

FIGURE 2.7: *NetBeans IDE.*

to do that. Nevertheless IDEs provide an easy and comprehensive way to build complex applications.

During this Thesis implementation both NetBeans IDE and Eclipse IDE were used. NetBeans was used primarily for the implementation of the Web Service. It is a lightweight IDE with easy to use interface that seems to be ideal for web development. Additionally, due to the JAX-WS plug-in the development of the Web Service was much easier, due to the additional functionality it provided. On the other hand, the Android application that operates as the client in this implementation was developed on Eclipse. Google provides a variety of plugins that work on Eclipse and make the development of an Android application a unique experience.

2.5.1 NetBeans IDE

NetBeans is a cross platform integrated development environment for developing applications primarily in Java. However, apart from Java other languages are supported as well. C/C++, Groovy, PHP and HTML5 are only some of those. NetBeans Platform allows applications to be developed from a set of components called modules. These modules provide a well defined functionality, such as syntactic support for a programming language, support for a versioning system like GIT or SVN, or other functionality that can be used during the developmental procedure. Users can choose to download NetBeans IDE bundles tailored to specific developmental needs or download a basic version of this software and install other features at a later time. Finally, from July 2006 through 2007 NetBeans was licensed under Sun's Common Development and Distribution License (CDDL), a license based on the Mozilla Public License (MPL). However, from October 2007, NetBeans was offered under a dual license of the CDDL and the GPL version.

2.5.2 Eclipse IDE

Eclipse is also a well known cross platform multi-language software development environment written mostly in Java. Additional functionality is provided by various modules that can be installed on top of it. One of these modules is the ADT plugin. This tool is designed to provide an environment suitable for the development of Android applications. ADT

extends the capabilities of Eclipse allowing easiest creation of the application's UI and offering a variety of other equally important tools.

2.6 Software Development Kit (SDK)

While developing an application the programmer might need a set of tools and libraries in order to be able to use a certain resource of the system, or just to implement a function easier using code that already exists. This set of tools is called SDK. Usually SDK is just an application programming interface (API) which is a set of files that are used in order to get access to already implemented code. For example, when developing an android app a set of methods may have to be called or implemented (interface) in order for the application to run on the specific platform.

SDK may also include a set of tools that are used from the IDE to produce a more appropriate coding experience which is suitable for the corresponding platform. It usually, also includes documentation files that provide information about specific functions and sample code for the developer to decrease its learning curve.

It should be mentioned that SDK licenses are a big issue that the developer should take into consideration if he is planning to distribute his application. The reason why this is so important is because many licenses are opposing. This means that some of the rules that the SDK license establishes might mean that the software built using a certain SDK cannot be distributed in a specific way. For example a GPL-licensed SDK will probably be incompatible with a propriety software.

Propriety software or closed source software is a computer software licensed under exclusive legal rights that limit the person to whom it has been granted the right to use the software in many ways. These restrictions include the prohibition of the user of the software to redistribute, modify, share, study, or reverse engineer it. On the other hand, a GPL-licensed SDK guarantees that the end users of the software built using this SDK will be able to do the aforementioned tasks without limitations.

2.7 Mobile Architectures

While in the past computers had to be disconnected from their internal network in order to be taken elsewhere, today mobile architectures provide the possibility to be always connected when transit. This, combined with the remarkable acceptance of mobile technologies from the public, results in the creation of an always-connected user

experience. Nevertheless, at this moment, there is without a doubt, a lack of a common industry view concerning mobile architectures. This is maybe caused due to the fact that this is a transitional period, since all these factors are completely new, therefore the industry has not found the time to adjust yet. This is particularly true considering the hardware of the mobile devices.

2.7.1 Platforms

Today there is a variety of mobile platforms available. The majority of these OSs are Linux based and the most popular ones are Android, iOS and Symbian OS. These OSs, just like any operating system, are responsible for the management of the hardware of these handheld devices. Access to the hardware resources are provided as services by the Operating System. The various applications use these services in order to be able to operate on the device.

Modern mobile operating systems allow the usage of the features that every conventional computer operating system provides, combined with additional features such the usage of touchscreens, cameras, near field communication, GPSs and many more. But the main issue with these operating systems is that they emphasize on low power consumption since the devices they run on are battery powered.

2.7.2 ARM Architecture

ARM is the most widely used architecture in mobile devices. In 2005 ARM was used in more than the 98% of mobile phones and was also used extensively in other devices too such as calculators, PDAs, media players, hand-held gaming consoles and so forth.

2.7.2.1 RISC architecture

ARM is a RISC architecture. RISC comes from Reduced Instruction Set Computing which is a CPU strategy based on the insight that simplified instructions can provide higher performance if this simplicity enables much faster execution of each instruction. Mainly, RISC uses a small highly-optimized instruction set instead of more complex instructions found in other architectures.

RISC term was coined by David Patterson of the Berkeley RISC project which started in 1980 but similar projects where proposed before that time. In 1964 Seymour Cray, who was an electrical engineer known as the architect responsible for the design of a series of supercomputers that were the fastest worldwide for decades, built the CDC

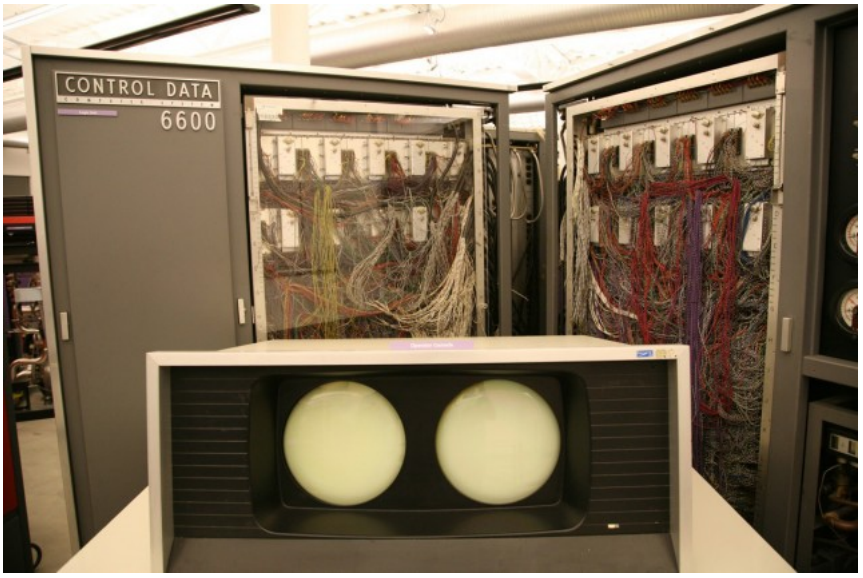

FIGURE 2.8: *Control Data Corporation (CDC) 6600.*

6600. CDC 6600 was a mainframe computer that used a load/store architecture with only two addressing modes and 74 opcodes. This mainframe is considered by many as the forerunner of RISC systems.

Berkely RISC used pipelining and a number of other famous techniques to achieve the increased performance, such as register windowing. Register windowing is a technique on which a computer system with a large number of registers such as 128 only uses a smaller amount of them (e.g. 8) on a procedure in order to accomplish faster procedure calls. Berkeley RISC developed RISC-I processor in 1982 which had 44,420 transistors when other architectures at that time used over 100,000 transistors. This processor had a great performance compared to other designs while the successor of this chip RISC-II a year later managed to be three times faster than RISC-I.

The well known MIPS is also a reduced instruction set computer architecture. The first steps of MIPS were in 1981 when faculty member John LeRoy Hennessy used it as a project for a graduate course which resulted in an architecture that by 1984 could run simple programs without problems.

2.7.2.2 ARM vs Intel

ARM's RISC is a very successful architecture that is used in a wide range of platforms from mobile devices to supercomputers, but at this moment the dominant platform on conventional PCs seems to be Intel's x86. The most important reasons for this are the following:

- From the very beginning of PC industry PC applications were written for, or compiled into x86 machines, while RISC does not have a similar installed base. As a result users where forced to stick with this architecture since in order for this to change a substantial amount of switching costs and discomfort would be required, not to mention the compatibility issues that would arise.
- In fact RISC architecture was able to scale up in performance quite quickly and cheaply, but Intel had vast amounts of money to invest in processor development. As a result the x86 architecture started developing in a much faster pace compared to the RISC architecture.

Since Intel's x86 is the dominant platform on PCs a reasonable argument would be why this does not apply to mobile devices. The main reason is that ARMs limited power consuption is ideal for the portable devices, on the other hand x86 platform requires a heavy power supply to power up the system. Of course x86 is usually more powerful than ARM but usually this is not an issue on mobile devices since the majority of the OSs used and the applications that run upon them are extremely lightweight. In addition, x86 is a very backwards compatible system which is expected from desktops, but the same does not necessarily apply to mobile phones and other mobile devices. Usually mobile devices roll out with a particular operating system pre-installed and the user rarely decides to change it.

Furthermore, ARM systems have an edge because as an open-licensed core, it has an entire ecosystem of vendors that provide solutions on specific areas, thus it has a great interface that allows it to connect easily with other devices. However, x86 chips are produced solely by Intel. As a result the device manufacturers are forced to use the components that Intel decides to bundle on their chips. Finally, this architecture supports java programming which is an important factor for its extended use. In addition, it should be noted that ARM processors are much smaller, making them ideal for mobile devices.

2.7.3 Mobile Development

Mobile application development is the process of developing a program which runs on low-power handheld device such as mobile phones, tablets and so on. These applications can come pre-installed by the manufacturer of the device or can be downloaded and installed from users afterwards. In addition they can be ordinary web applications that run within the browser and may have been optimized for mobile use.

Applications were originally offered for general productivity and information retrieval by their users. In the beginning, apps were used to view mails, weather conditions, calendars and more, but later the public demand combined with the availability of the advanced developer tools concluded in a broader range of categories such as mobile games, mobile ticketing, social networking, e-banking, geolocation services and so on.

In addition web developers took into account the large rise in mobile device usage and started building web applications optimized for small screens. Thus, there were no restrictions concerning what operating system is used since the only program that is needed for a web application is a web browser, which usually comes pre-installed on every device. One more advantage of mobile optimized web applications is that they do not require an installation and as a result no storage space is needed, although it is usually required to download a certain amount of data in order to run properly the cache can be cleared after the application has been used, freeing all used space.

Of course there are some disadvantages when using web applications instead of native ones. Firstly, web browsers require to navigate into a specific web address. As a result internet access is required at all times. This is an important disadvantage since there is not always a WiFi available and 3G/4G data plans remain expensive in many countries not to mention that 3G/4G signal is very limited in some locations. On the other hand native applications can run entirely locally without requiring internet access. In addition, as mentioned, web applications require navigation into a specific address which means that typing is almost always required. This is usually not an issue when using a PC but typing in a mobile device with a small touchscreen can be very inconvenient, typing errors are easy to occur ruining the user experience of the application and causing discomfort. On the other hand native applications either run entirely locally, so they do not require any typing to connect, and even if they require some kind of online transaction with a remote server they usually connect instantly in a predefined address when opened by the user. Finally, native applications may use some extra space on the memory of the device but they usually need a lot less internet usage in order to do the same tasks that a web app does. This is caused due to the fact that usually when using a web application the whole user interface has to be downloaded in order to be rendered by the browser. On the other hand a native application, which requires internet access, only needs the data from the server side since it is responsible for rendering them correctly.

As we mentioned earlier, the developer usually uses an IDE in order to be able to implement the application he wants easily and without concerns that have to do with make-files, inclusion of the right libraries and so on. In addition, he needs the appropriate

SDK for the platform on which the application will run. In order to be able to test the application, the developer needs to either use a testing device or an emulator.

Emulators are an inexpensive way for the developer to test his application on the computer he uses to develop it. Usually these emulators are provided by the SDK without any additional fee. When the programmer decides to use an emulator usually a window appears that has the appearance of a phone with a fully functional operating system. This means that even if the user cannot make calls he can navigate into the applications, folders and settings of the virtual phone and test his application.

Another way of testing an application, is by using a physical device. Of course, this is not always possible as the developer might not own a testing device. Additionally many platforms, such as Apple's iOS, require an extra fee in order to run the created application into a physical device. Nevertheless, it is advised to test the application into a device before publishing it, in order to make sure that no bugs appear on it.

2.7.4 Android Development

Android uses Activities to show the UI of the applications. It is a single focused screen the user can interact with. The programmer has in his disposal some standard functions to manipulate the behavior of this screen during the various stages of the application.

These various stages of an application, are known as the Activity's Lifecycle. Activities are managed using an activity stack. When a new activity is started, it is placed on the top of the stack, which contains other running activities. An activity remains below another newly added Activity until the later one exits. At that time the older Activity returns to the foreground.

2.7.4.1 Activity Lifecycle

Activities can rotate between four stages:

- **Active or Running** is an activity that is placed at the top of the Activity Stack. The UI of this Activity is shown to the user and he/she can interact with it.
- **Paused** is an Activity when it has lost focus because another non-full sized or transparent Activity is on top of it at the Activity Stack. A paused Activity is considered to be alive keeping the state and the variables it had before, but if the OS decides that there are extremely limited resources it will be terminated.

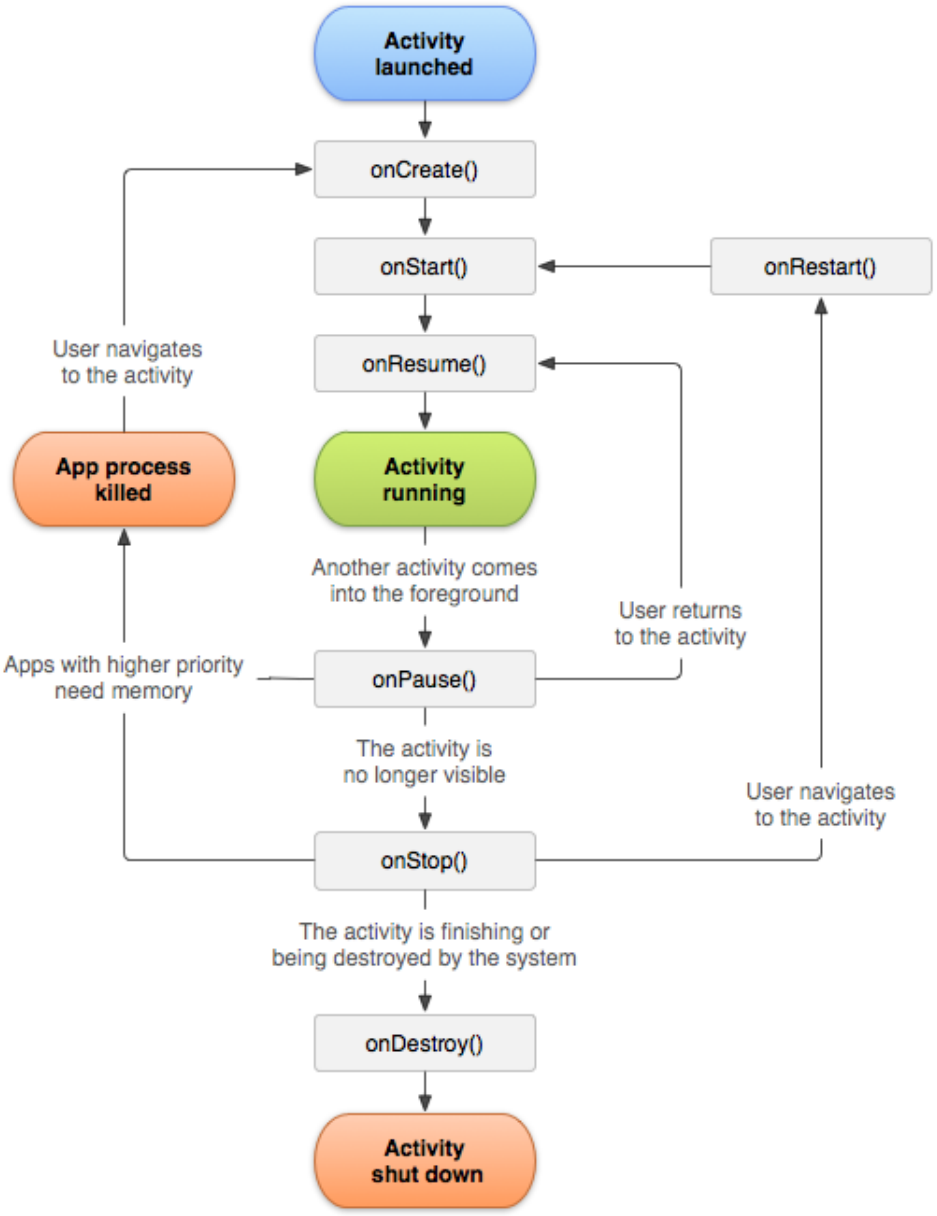

FIGURE 2.9: *Activity States with Callback Methods.*

- **Stopped** is an Activity when it is completely covered by another one. In this state the Activity is not visible to the user and is considered to be stopped until the OS decided to kill it due to limited resources.
- When an Activity is either stopped or paused and the resources are coming to an end, the OS "asks" the Activity to finish. If this does not happen it is killed by the OS. When the user resumes this terminated Activity must be completely restarted and restored to the previous state.

Callback methods, if implemented enable a programmer to perform operations during the transition of the Activity from one state to the other.

The three loops that a programmer should be aware of while developing an Android application are the following:

- The **entire lifetime** of an Activity happens between the first call to onCreate() through the final call to onDestroy(). This means that an Activity will do a setup of the state and the resources that will be required on onCreate() and will release the resources on onDestroy(). For example, in the application developed for this Thesis, at one point an Activity creates two background services that are responsible for sequential calls to the Web Service. When this Activity reaches its final stage these two background services must be stopped and another request has to be sent to the Web Service to terminate the operation that is executed. All these operations occur on the onDestroy() function.
- The **visible lifetime** of an activity happens between a call to onStart() until a corresponding call to onStop(). During this time the user can see changes to the Activity even if it is not on the foreground. It is a good practice to create an operation that is influenced by such changes at the onStart() function and destroy it on the onStop() function as no changes will occur after this function is called.
- The **foreground lifetime** of an activity happens between a call to onResume() until a corresponding call to onPause(). During this period the Activity is in front of other Activities and interacting with the user. A great example that shows the meaning of this cycle is the following: If an Activity is changing constantly, for example a graph is being drawn in real-time, and the device goes to sleep, the interface will keep changing even if the user cannot see any change. This results in a higher power consumption and an overall bad implementation. The drawing of the graph can be paused on the onPause() function and resumed when the activity regains focus if a s without losing any values.

At this point it has to be mentioned that an application does not necessarily implement all those methods. Many of them can be omitted as long as the application runs correctly without crashing, consuming valuable resources when they should be free and so forth.

2.7.4.2 Screen Sizes in Android

Android is intended to run on devices with various screen sizes and the same applies to the Android applications. This fact can cause problems on some Activities and a special

care should be provided from the programmer. This special care may include alternative resources that optimize the user experience on every available screen size.

Two general properties categorize the screen of every device: size and density. The size of a screen can be small, normal, large or extra large and the density can be low (ldpi), medium (mdpi), high (hdpi) or extra high (xhdpi).

Special directories are provided for the necessary resources, which have to be properly scaled to the various density buckets. The appropriate scale for each density bucket is:

- xhdpi: 2.0
- hdpi: 1.5
- mdpi: 1.0 (baseline)
- ldpi: 0.75

This means that if an image is required in 20x20 dimensions for an xhdpi screen the same image must be created in 15x15 for an hdpi screen, in 10x10 for mdpi and in 7.5x7.5 for ldpi screens.

2.7.4.3 Different Platform Versions

Android is constantly under development. This results in a broad range of changes on the various methods and functionalities from one version to the other. While from one perspective this is a positive feature, as it means that bugs and security issues are resolved, the changes made from one Android version to the other, may require specific code for a functionality to run properly, that depends on the version of Android.

Android and Google offer to the programmer tools that show real-time stats of the devices that interact with Google Play, which is the store a user can visit to download new applications. These stats can be useful to a developer as they give information concerning which Android versions should be supported the most. If an Android version is installed on the vast majority of the device that interact with this store, then it certainly is advised for this version to be supported.

During the development of the Android application of this thesis this problem arose several times. Apart from the fact that some functions where no longer supported on later versions of Android, or they are deprecated, which meant that this specific part had to be implemented differently. Some functions, changed drastically causing crashes when run on versions different from the one used for testing.

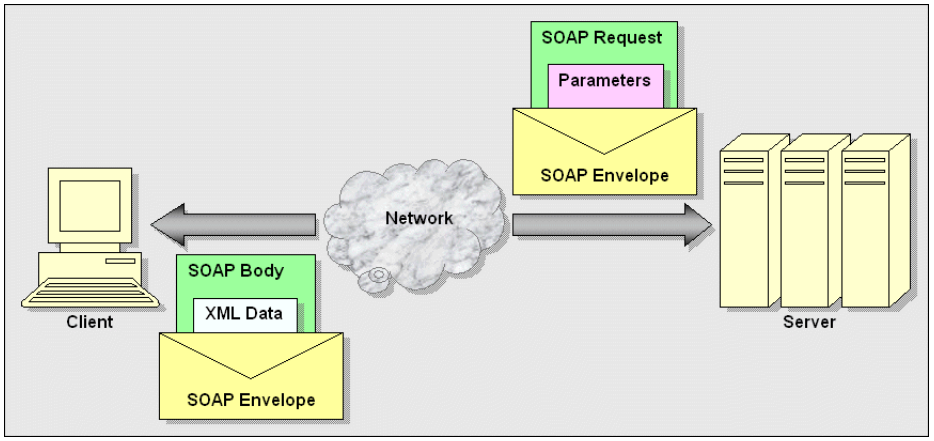

FIGURE 2.10: *SOAP Web Services.*

Android allows the programmer to specifically set the supported versions of Android but this certainly does not solve the problem. As a result many blocks of code had to be version specific. Thankfully, Android provides functionality that can make this process easier, as a simple function can return information about the system of the device, but again this version specific code at times is so extended that has resulted in many problems on the Android community.

At the time, these lines were written a bundle had just rolled out from Google that included libraries used in previous versions of Android. The purpose of this bundle is to allow the programmers make applications backwards compatible easier, but again this may end up creating more problems.

2.8 Web Services

Web Services enable the communication between two electronic devices over the World Wide Web. According to W3C a Web Service is "a software system designed to support interoperable machine-to-machine interaction over a network". To enable this over-the-network interaction, many protocols can be used including but not limited to HTTP. There are two known types of Web Services, SOAP based and REST. Both of which will be analyzed here.

2.8.1 SOAP Based Web Services

Typically, they provide an interface described in an XML-like document called Web Services Description Language (WSDL). This document in particular is used to describe

the functionality offered by the service and the rules the clients need in order to make valid requests to the Web Service and receive responses in a predictable format.

More specifically, WSDL describes services as a collection of network endpoints, or ports. A port is defined by associating a network address with a reusable binding, and a collection of ports defines a service. Messages are abstract descriptions of the data being exchanged, and port types are abstract collections of supported operations.

WSDL is usually combined with SOAP and an XML Schema to provide Web Services over the internet. Clients are connected to a Web Service by accessing the WSDL file. That way the client can determine what operations are offered by the service provider. SOAP is used in order to call one of these operations using XML files or other binding mechanisms.

There are two types of SOAP requests. The first one is Remote Procedure Call (RPC) style requests, which usually is synchronous. By synchronous we mean that the client transmits a request and waits for the response from the server. The second type is the document request. In this type of SOAP request, a complete XML file is transmitted from the client to the server and a response, which once again is an XML file, is returned.

2.8.1.1 RPC

SOAP-RPC is an implementation of a Remote Procedure Call. In this case, there is an inter-process communication that allows a program to call a subroutine to execute in a remote computer as if it was a local function. Additionally, the programmer is not obligated to write code for the various details of this interaction. He just follows some specifications and writes the same code he would write if this function was executing locally.

This communication is initiated by the client. The client sends a request to a remote server, including the parameters that would be sent if the function was executed locally. After the server processes the data included in the request message it sends a response. During this time, the client is blocked, it cannot go on executing the rest of the lines of code as it has to wait for the service to respond. This of course, applies to the cases where no asynchronous mechanisms are used.

Some worth-mentioning problems that may occur during this interaction, which cannot occur during a local function call are the various network problems. The challenging part usually is the fact that during these network failures the clients cannot know if the remote procedure was actually invoked or not. In this case a simple recall would solve

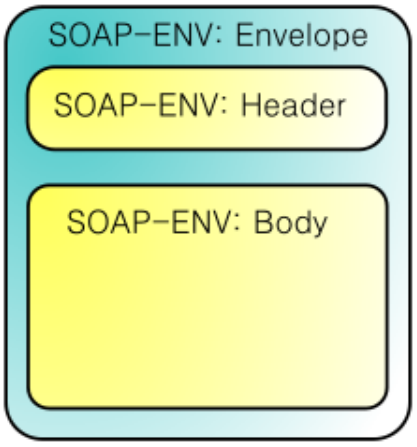

FIGURE 2.11: *SOAP Structure.*

the problem but this does not apply to the occasions where the procedures have different functionality depending on the number of times they are called.

2.8.1.2 Document Transmission

In this type of message exchanging a complete XML document (or a document created as a part of another marshaling-unmarshaling mechanism e.g JSON in a SOAPjr Service) is transmitted as the body of the SOAP message instead of simple parameters. A schema common to both the sender and the receiver is used to encode and decode the data. When responding to the request, the server side does not send just a single returning value, instead, a complete document is sent that contains all the information that a normal invoice would have, the difference is that in this case the document is marked-up and machine readable.

This style of messaging has some advantages over the RPC style messaging. For starters, RPC callings are relatively static. If the service provider decides to change the RPC interface, even slightly, he will break the contract between the server and the client. As a result an application that has the role of a client in an RPC service will malfunction. On the other hand, the rules on a document transmission are more flexible and less rigid.

On a document exchange that uses XML, changes can be made to the XML schema used to bind the data, without resulting in a faulty communication between the server and the client. The changed XML document will be transmitted and the new XML schema will be used to unbind the data, without causing problems to the transmission of the data. Furthermore, since in this case the message is a self contained document, it is more suitable for an asynchronous communication.

2.8.1.3 The Structure of a SOAP Message

SOAP messages are essentially an XML document consisting of an <*Envelope*> root element, an optional <*Header*> element and a mandatory <*Body*> element. Inside the <*Body*> element can be found a <*Fault*> element when reporting errors.

Header element is used to pass application related information, such as authentication and payment details. If this element is present it has to be the first child element of the *Envelope* element. The SOAP specification does not strictly define the contents of the *Envelope* element, but it can include routing information of the SOAP message.

```
<?xml version="1.0" encoding="iso-8859-1"?>
<soap:Envelope xmlns:soap="http://schemas.xmlsoap.org/soap/envelope/">
 <soap:Header>
  <wsse:Security xmlns:wsse="http://schemas.xmlsoap.org/ws/2003/06/secext">
   <wsse:UsernameToken wsu:Id="myUs3rn@met0k3n"
       xmlns:wsu="http://schemas.xmlsoap.org/ws/2003/06/utility">
    <wsse:Username>myUs3rn@me</wsse:Username>
    <wsse:Password Type="wsse:PasswordText">th1s1s@p@ss</wsse:Password>
    <wsu:Created>2012-05-19T08:44:51Z</wsu:Created>
   </wsse:UsernameToken>
  </wsse:Security>
  <wsse:Security soap:actor="oracle"
      xmlns:wsse="http://schemas.xmlsoap.org/ws/2003/06/secext">
   <wsse:UsernameToken wsu:Id="oracle"
       xmlns:wsu="http://schemas.xmlsoap.org/ws/2003/06/utility">
    <wsse:Username>usern@m3</wsse:Username>
    <wsse:Password Type="wsse:PasswordText">p@ss</wsse:Password>
    <wsu:Created>2012-05-19T08:46:04Z</wsu:Created>
   </wsse:UsernameToken>
  </wsse:Security>
 </soap:Header>
 ...
</soap:Envelope>
```

Listing 2.1: SOAP Header Example

The *Body* element is where all the information that must be transmitted are stored. This part of the SOAP message is mandatory and only one child element is defined by the SOAP protocol. This is the *Fault* element which is used for error reporting.

If the *Fault* element exists, it can appear only once in the *Body* element. The sub-elements of this element are defined differently in SOAP 1.1 and SOAP 1.2, but in both protocols the *Code* of the fault is included. This *Code* specifically defines the error that occurred and it can be processed by software. Apart from *Code* another element is included which contains the reason why this malfunction happened. This element contains a description of the problem and it is intended for a human reader. Other elements specifically point out the SOAP node that created the fault, the role it had

and other details concerning the problem. The programmer can use these error codes while developing the client application and the web service or he can use other structures, which he has to define by himself with an XML schema, that describe the problem

```
<soap:Envelope xmlns:soap="http://www.w3.org/2003/05/soap-envelope"
   xmlns:xml=http://www.w3.org/XML/1998/namespace
   xmlns:wsa="http://schemas.xmlsoap.org/ws/2004/08/addressing"
   xmlns:dsc="http://schemas.microsoft.com/windows/2008/12/wdp/
   distributedscan/configuration">
   <soap:Header>
      <wsa:Action>http://schemas.xmlsoap.org/ws/2004/08/addressing/fault</wsa:Action>
      <!-- Headers excluded for brevity -->
   </soap:Header>
   <soap:Body>
      <soap:Fault>
         <soap:Code>
            <soap:Value>soap:Receiver</soap:Value>
            <soap:Subcode>
               <soap:Value>dsc:ClientErrorJobTokenNotFound</soap:Value>
            </soap:Subcode>
         </soap:Code>
         <soap:Reason>
            <soap:Text xml:lang="en">A PostScan job identified by the
            specified dsc:JobToken argument could not be found.</soap:Text>
         </soap:Reason>
      </soap:Fault>
   </soap:Body>
</soap:Envelope>
```

Listing 2.2: SOAP Body Example that contains Fault element

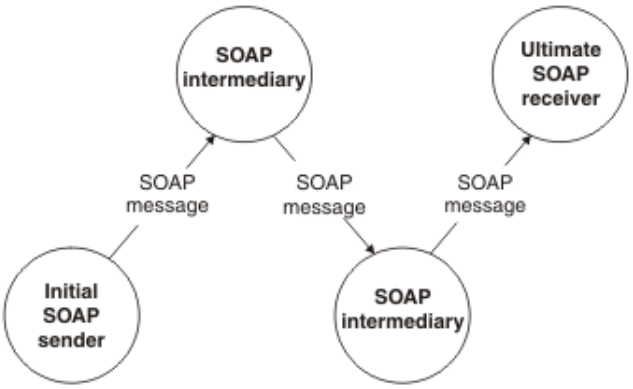

FIGURE 2.12: *a SOAP message path.*

2.8.1.4 The SOAP Message Path

Typically a network is composed by many computers that are used as nodes and the same principles apply to the Internet. This means that when a message is sent from one computer to another this message will bypass other computers until it reaches its final destination. These intermediate computers are known as nodes and the sequential arrivals-transmissions that are made by these nodes are known as hops. The same principles apply while sending SOAP messages.

SOAP message path is the set of nodes through which a single SOAP message passes until it reaches the destination. Both the initial sender and the ultimate receiver are included in this set, so in its simplest form this path includes just those two nodes.

2.8.2 RESTful Web Services

Apart from SOAP Web Services, there is another type called RESTfull (REpresentational State Transfer Service). The primary purpose of this service is to manipulate representations using a uniform set of "stateless" operations. It describes architectures that use HTTP or other protocols by constraining the interface to a set of operations, such as GET, POST, PUT and DELETE.

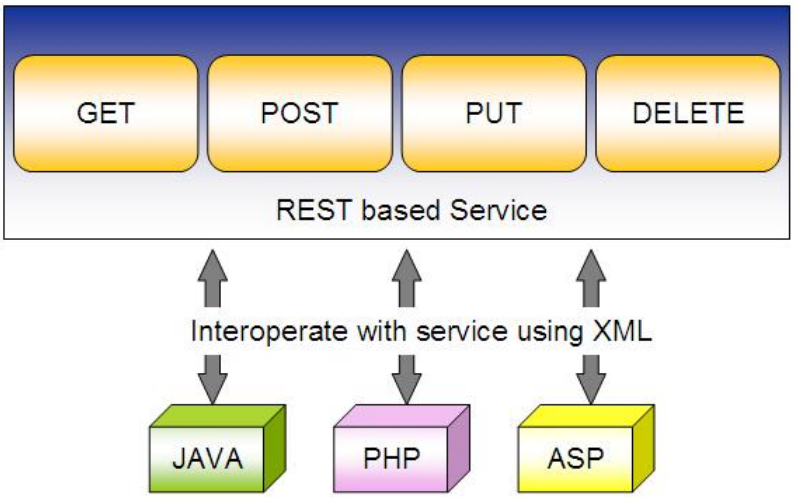

FIGURE 2.13: *RESTful Web Services.*

State is a technical term used to describe a set of stored information, at a given point in time to which a program has access to. As the Web Service is called from different clients, it is a better approach to consider every request as a new one. This results in a less complex and a "cleaner" service with a more predictable behavior. An implementation which has the above-mentioned characteristics is considered stateless.

As all service do, REST services provide access to resources. A client uses a way to identify the resources that are needed, such as using URIs when interacting with a web based REST service. Later, a representation of the requested resources is returned to the client. Usually these resources are returned in a form that allows them to be recognized and manipulated correctly by the client. Standard ways to represent the data in order to be transmitted are HTML, XML or JSON bindings. Apart from the format of the returning information, the identifier of the resource and the action required, the client does not need to know any network-specific information. For example, the calling application does not need to know any details considering whether or not there are caches, proxies or other elements between the client and the service.

In a REST service the client is in command. When a client has in its disposal a representation of a resource, it also has all the needed information that would allow it to make a modification or even delete the entire resource from the server, provided that it has the rights to do so.

Hypermedia as the Engine of Application State (HATEOAS) is one of the constraints of the REST application architecture. The main principle is that the client can interact with a server side application using hypermedia generated dynamically by the service. As a result, a REST client can interact with a server without prior knowledge of the

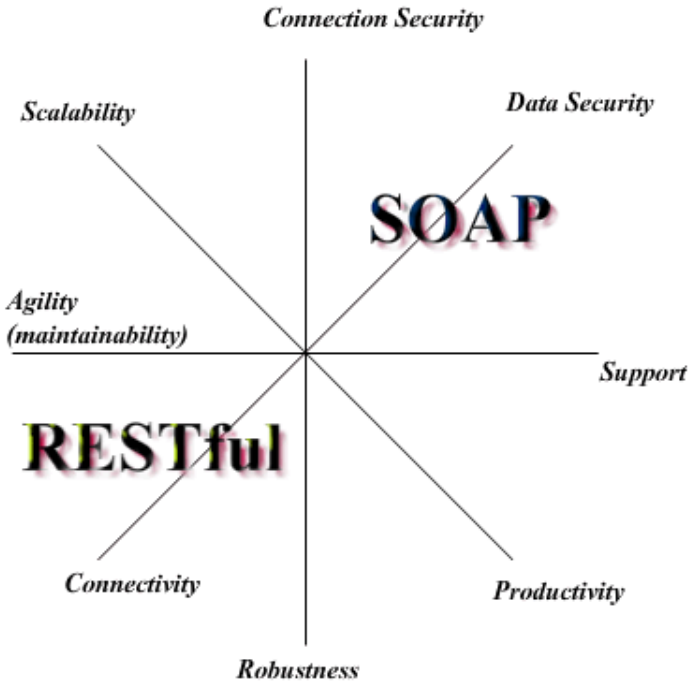

FIGURE 2.14: *REST vs SOAP.*

interface used by the service. Apart from some fixed endpoints that usually are known in advance, a client uses the information retrieved by the service in order to proceed using and manipulating the resources provided. This opposes to the way SOAP services operate, as a specific contract in a form of a fixed interface is used to provide information concerning all the available functionality of the service.

2.8.3 REST vs SOAP

Although, Web API is moving away from SOAP based services and more into RESTfull, in this thesis implementation, we chose to build a SOAP Web Service. There are many advantages and disadvantages of both these types of services.

Firstly, REST services are indeed very lightweight. They are not as complex as SOAP services are, but despite the fact that they are very light and easy to implement they are not as secure as SOAP services are. SOAP services have been a standard for many years, they have been used ceaselessly by many service providers and there are many APIs that can be used to build great services, especially in JAVA.

A certain drawback that SOAP services have is that they require more bandwidth than REST services do, since XML is primarily used for the interconnection between the client and the server, more data are transmitted. The messages transmitted in a SOAP

service include information that is seemingly useless and can be avoided. This is utilized in REST services but since in our case the transferred data are not that big and since we had the chance to exclude some of the unused data from the XML messages, these disadvantages were limited to the minimum. Apart from that, the security factor of SOAP services gave a certain advantage.

Furthermore, as SOAP services have been used for more years than REST services, there are many tools available to choose from and many bugs and problems have been eliminated over the years. Additionally, since the greatest part of the processing of data, during this interaction between the server and the client, is performed on the server side, as opposed to REST services, (where more workload is brought upon the client side) the SOAP approach was preferred. The reason why SOAP was preferred is that in our case the client is a mobile application, that runs on a device with limited capabilities, while the server is a much more powerful machine.

Additionally, as we mentioned there are many APIs and tools available for building a SOAP web service, this results in more features that can be utilized. For example as we mentioned before, a standard way of using a web service is: a client makes a request to a specific address and after a while the server side responds to that request with the available data. This surely seems to be more than simple but what happens when the server side needs to send data to the client without receiving a request? If for example an event occurs on the server side, that would trigger a process during which information should be returned to the client without any requests from it, there could be a problem. In a SOAP service this is no issue. Asynchronous communication can be implemented by a couple of methods, and can solve this problem.

2.8.4 (Un)Marshalling

Usually the intermediate level, has to operate on data related to an object. This object has to be transmitted to the client but in order for this to happen it must be encoded in some way that will make the communication between the server and the client easier. This is done by marshalling. Marshalling is the conversion of an object into a data structure such as an XML, JSON or other formats in order to transmit it or to store it. Unmarshalling is the reverse procedure but it is common to refer to both types of conversion as marshalling.

Marshalling is also considered synonymous with the term serialization. This is not entirely true since marshalling records the state and the codebase in a way that when this object is unmarshalled a complete copy of the original object is obtained including, in most cases, the class definition of an object. On the other hand serialization is just

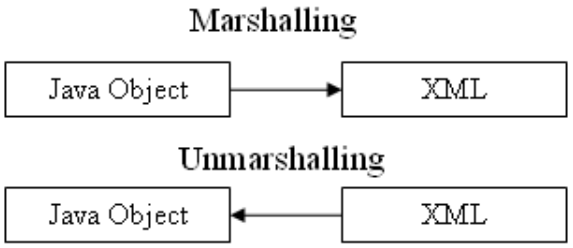

FIGURE 2.15: *(Un)Marshalling.*

the procedure of converting an object into a byte stream in a way that can be easily reconverted back into a copy of the object.

                                "GlossDef": {
                                "para": "para element.",
                                        "GlossSeeAlso": ["GML", "XML"]
                        },
                                "GlossSee": "markup"
```

```
18                  }
19                  }
20          }
21    }
22 }
```

Listing 2.4: Example of an JSON representation of the Same Resource

2.9 TinyOS Architecture

TinyOS is an open source, BSD licensed operating system specially designed for low-power wireless devices. The main difference between this architecture and the one used in traditional Operating Systems is that the requirements of the later system are too demanding.

Specifically, in a traditional OS there are large memory and storage requirements in order to support functionalities that seems rather useless for a sensor mote. Additionally, a standard Operating System is undoubtedly too complex and power consuming for a wireless device.

An ideally designed device for our purpose should have efficiency as a main attribute, in order to run as a node on a sensor network. By efficiency, we mean that we want an architecture with a small footprint, with a low system overhead and certainly with a low power consumption, as those characteristics are crucial for every remote/mobile device, because these devices are intended to run solely on batteries and it is intended to do this for a long period of time. Apart from these elements, all the rest that are usually found on the majority of the Operating Systems intended for use on a PC, such as a subsystem responsible for the UI, are just a burden in our case.

TinyOS is ideal for running on low power motes, as it is bundled with all the required components, but without the extra weight of the unnecessary ones. TinyOS does not include a kernel. This means that there is a direct hardware manipulation that limits the resources needed for the completion of a task and at the same time, this immediacy, although it seems to lead to a somewhat low level programming, at the end of the day, it serves well its purpose.

The unnecessary system overhead is stripped down by a number of other ways too. Firstly, there is no process management as there is only one process needed that runs on the fly. Furthermore, there is no virtual memory as it is simply not needed. There is just a single linear physical address space. What is more, there is no dynamic memory allocation mechanism, which means that the memory is assigned at compile time. This

system although very efficient, it can be dysfunctional if the image of the program that runs on this systems ends up being too big. So the programmer should make sure that the application will remain small. Additionally, other problems may occur due to memory issues that may result in faulty behavior of the program while running.

When applying a closer look on TinyOS, one can notice that there is a certain separation of construction and composition. Components contain "slices" of code responsible for a specific functionality. Apart from the applications, the libraries are also bundled in components. Two or more components are wired together using an interface.

The programming language used for the synthesis of those components is nesC. NesC is a language that resembles C but some additional features, are added to fully support the functionality needed in TinyOS.

2.9.1 Interfaces

In the TinyOS framework a component can either provide or use an interface. Interfaces describe a logical related set of commands and events. When a component provides an interface, it provides a functionality to the component that uses it. The used interfaces represent the functionality the components need in order to be able to perform the task they are intended to.

In TinyOS interfaces are bidirectional. This means, that interfaces provide a set of commands that have to be implemented by the interface's provider and a set of events that have to be implemented by the component that uses a particular interface, otherwise an error will occur. Additionally, a component can use or provide multiple interfaces and multiple instances of the same interface. The set of interfaces a component uses and provides is called that component's signature.

2.9.2 Modules & Configurations

Modules and Configurations are two types of the components found in TinyOS. Modules provide the source code, the implementation of an interface, while configurations are used to assemble components together. Typically the process of connecting interfaces used by a set of components with interfaces provided by others, is called wiring.

2.9.3 Singletons & Generic Components

Two other types of components in TinyOS are singletons and generic components. Singletons are unique, they exist in a global namespace and as a result they can only

exist once, while generic components can have multiple instances. Two configurations that use the same singleton component are essentially accessing the same variables.

2.9.4 Events & Tasks

Another interesting set of features in TinyOS is the asynchronous events and tasks. Tasks cannot preempt each other, events can preempt tasks since they have a higher priority and events can preempt each other once enabled. This is critical in many ways. If for example two messages arrive at the same time to a mote, the appropriate event will get fired twice overriding the variables formerly containing useful information. This will have as a result the loss of one of two messages. If on the other hand, the data included on the messages are instantly copied to other memory locations, as soon as the events are fired and tasks are posted to process these data,they will not be overridden and no data loss will occur. TinyOS scheduler runs tasks one by one in the order they are posted until their completion.

Chapter 3

Requirements Analysis, User Interface Prototyping and Evaluation

3.1 Introduction

Before the implementation of every application begins, a set of requirements has to be defined. Designers should be able to visualize the product along with the functionality it will provide. It is important to clarify what exactly the product is about. "What is the problem this application is about to solve?", and "how does this application solve the problem in a better way than other products?", are questions that should be answered before continuing to the implementation.

After having answered these questions, we can go to the next step, which is the actual design of the interface. Usually the developers have a specific model of the final product in mind, which they know that can be implemented (since they have the technical skills) and they believe that it will be adopted by the end-users. Unfortunately, this usually is far from the truth. Programmers are not always the most representative users. If the final product has as a target group, tech-savvy people, then programmers may be the best for this job, but if this is not the case their final design will probably not be that good. It is therefore significant to use real users to evaluate the interface.

By creating paper prototypes, the developing team can easily brainstorm on the design of the application and later, use these prototypes to evaluate the interface. This method is easy, fast and efficient. The prototypes are created easily, in just a few minutes or hours at most, and after they have been evaluated by the users, it is also easy and fast

to make adjustments on them or to throw them away and create new ones from scratch to solve potential problems. It is noteworthy that the alternative would be to implement the entire application, use real users to evaluate it and then make adjustments. That would require too much time if major changes were required, so it is preferable to spot design errors from an early stage and solve them before they reach the next stages.

In this chapter, we describe the entire process of requirement analysis, paper prototyping and evaluation using real users. Additionally, more information about other techniques such as personas, storyboardings and more will follow.

3.2 Personas

Personas are fictional characters created to imitate the users of a product. By analyzing the special characteristics and attributes of a persona, the designer is able to understand the requirements of the product and the criteria that must be met in order to be successful.

Particularly, instead of having an abstract idea about potential users the designer puts a face on a representative sample user. Instead of dealing with abstract imaginary users, he has to deal with a specific person, that has a particular educational background, certain needs and concerns and a specific ability to adapt to new technologies.

This process in overall leads to a better understanding of the users. Usually, developers put themselves in the user's position in order to be able to figure out the interface of the application they are building. However, the developers may have nothing in common with the target users and as a result it is rather doubtful that this product will eventually satisfy the needs of the target group. By using personas, on the other hand the entire developing team tries to figure out the unique characteristics of the end user and create a design that suits him and covers his needs.

Bellow, there is a extensive analysis of the personas used for this specific application.

3.2.1 Anne, 41, Professor

FIGURE 3.1: Professor Anne

Name: Anne

Age: 41

Research Interests:

- Advanced compact MOSFET models
- Analog—RF integrated circuit design
- RF characterization & modeling of nanoscale electronic devices

Professional Service: Regular reviewer for IEEE Trans. on Electron Devices,IEEE Trans. on CAD of Int. Circuits and Systems.

Teaching:

- **ACE 506**: Design of CMOS Analog Integrated Circuits
- **ACE 604**: Special Themes of Analog IC Design

Anne is a well-known researcher of the field of electronics. She received her bachelor's degree from the National Taiwan University and her Ph.D. in electrical engineering from U.C. Davis. She has a long list of publications on her field of interest and she is currently working into a revolutionary method of constructing a transistor that will lead to a radical increase on the processing power of CPUs.

Anne uses PCs and smartphones into her everyday life. She is certainly able to use applications that do not have the most user-friendly interface, but she definitely prefers to use web and mobile applications with a sleek, easy to use interfaces that follow the design patterns used by the vast majority of today's applications.

She might be interested in this product as it will help her in the research she currently does. Electrical circuits and transistors are easily affected by the environmental conditions. Her lab does have all the necessary equipment to measure the temperature and humidity in the room were it is placed, but the problem is that she is not always in her lab. She has many responsibilities, such as preparing for lectures, office hours, attending workshops and seminars, that force her to spend time outside of the lab.

On the other hand she is concerned that her T.A. students that have access to the lab might change the temperature of the room, and cause critical problems to her work. This application allows her to endlessly monitor the conditions of the lab at any time.

She could be traveling to another country in order to attend a conference or she could be at her house relaxing after a long day, and she could still be positive that her project remained intact. Additionally, the outlier detection algorithm helps her notice any abnormalities that may occur in her lab, again from any location.

3.2.2 John, 63, Businessman

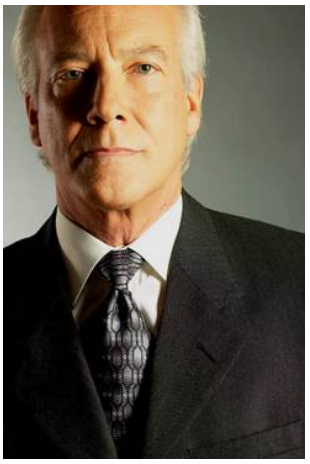

FIGURE 3.2: Mr. John

Name: John
Age: 63
Education:

- University of Phoenix
- University of Wisconsin-Madison - School of Business
- Shasta College

Currently: President and Founder at Johnson - Murray and Sons, Inc. & Real Estate Consultant & VP of Luxury Home

John is a businessman with many years of experience in the industrial world. He is constantly talking with his associates from around the globe on the phone and is always on the go. The airports are his second home, as he travels a lot in order to take care of all his business matters.

John, does not like computers. Since, he is used in traveling a lot, he feels constraint while using them, even laptops seem inconvenient to him as they are rather heavy to carry around at all times. Additionally, their battery life is not that good and he has to recharge them constantly. On the other hand, John has always with him his smartphone because it allows him to check his mail and communicate with his associates free of charge.

He might be interested in this product because he currently is the president of a well-known firm, that recently bought a building to use as a factory. In this factory, expensive but sensitive to high temperatures equipment will be used and he is worried that if he does not take special care of the indoor temperature and humidity the equipment will be ruined. Since this is a new factory in a foreign country he does not know if there is anyone responsible enough to take care of this problem for him, so he has to do it by himself.

This product will allow him to keep taking care all his business matters without worrying about the equipment of this factory. If he is worried, he can just check the temperature on each and every one of this factory's rooms and make sure that everything is fine. If on the other hand, a problem occurs the outlier detection algorithm will help him find out that there is a problem and either get to the factory by himself to solve the problem or send one of his assistants.

3.2.3 Katia, 23, Undergraduate Student

FIGURE 3.3: Ms Katia

Name: Katia
Age: 23
Education:

- Undergraduate student at the Conservation of Antiquities and Works of Art Department at the Technological Educational Institute of Athens
- 23th High-school of Athens

Currently: Working as an intern at the Academy of Athens and at the same time working on her Thesis assignment.

Katia is a young female student that currently works as an intern at the Academy of Athens. As every young energetic 23-year-old she is an excellent user of technology related products. She always carries around her smartphone and she is always connected with her friends over social networks.

Apart from that, Katia although not a poweruser, she considers her smartphone to be a very powerful tool, and she uses it as such. When she is lost or just trying to get from point A to point B using public transportation she uses Google Maps, she checks her mails on the go, reads news portals and uses other programs to make her life easier.

She might be interested in this product because at the Academy of Athens where she currently works, the administrator has set up a number of sensors. She along with the administrator can be held responsible for the monitoring of the conditions of the room where delicate ancient artwork is positioned. These artifacts under the right conditions can be preserved for a very long time, and since the room in which they are placed is used as an exhibition room, this system can ensure that the criteria for the ideal conditions will be met.

3.3 Storyboarding

Storyboarding in Software Engineering is used to describe the specifications of a particular software. During this phase, the user interface of project is decided, or to be more precise, an early stage of that interface. These prototypes can take less than a day to be completed for an entire system, as opposed to a finalized software system. They are easy to share at large groups and they do not give the false impression that the system is already developed. After all, the project is just at the beginning and this phase exists just to make sure that the developing team is pointing to the right direction. The users that are going to have access to the storyboards during the testing phase should feel that it is something easy to create and throw away. That way it will be easier for them to give a negative feedback, if necessary.

Storyboards are performed in many different ways. They sometimes are created electronically, although they may end up taking too much time and ending up looking too detailed for their purpose, or they could be little sketches on white boards or on papers. Usually, they look like raw comics, a simple picture of an interface that includes the buttons and figures that are going to be positioned there is more than enough. Of course, they could even include drawings of people using the software on their everyday lives, it is up to the developing team to use it in the way that suits them, it can even be used to boost the morale and bonding of the team, but it is vital to be understandable by the users.

The following images illustrate how this project was initially conceived, and how the requirements were set at first.

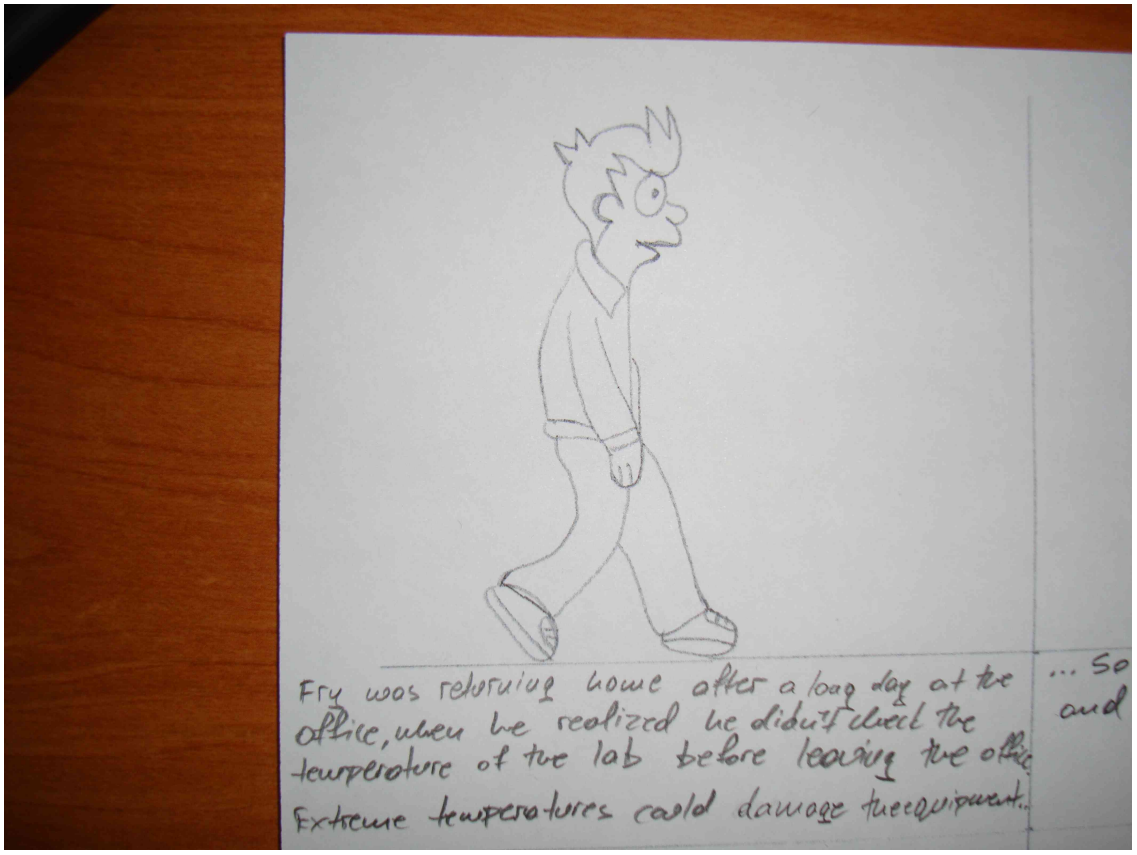

FIGURE 3.4: *Storyboarding 1st Image.*

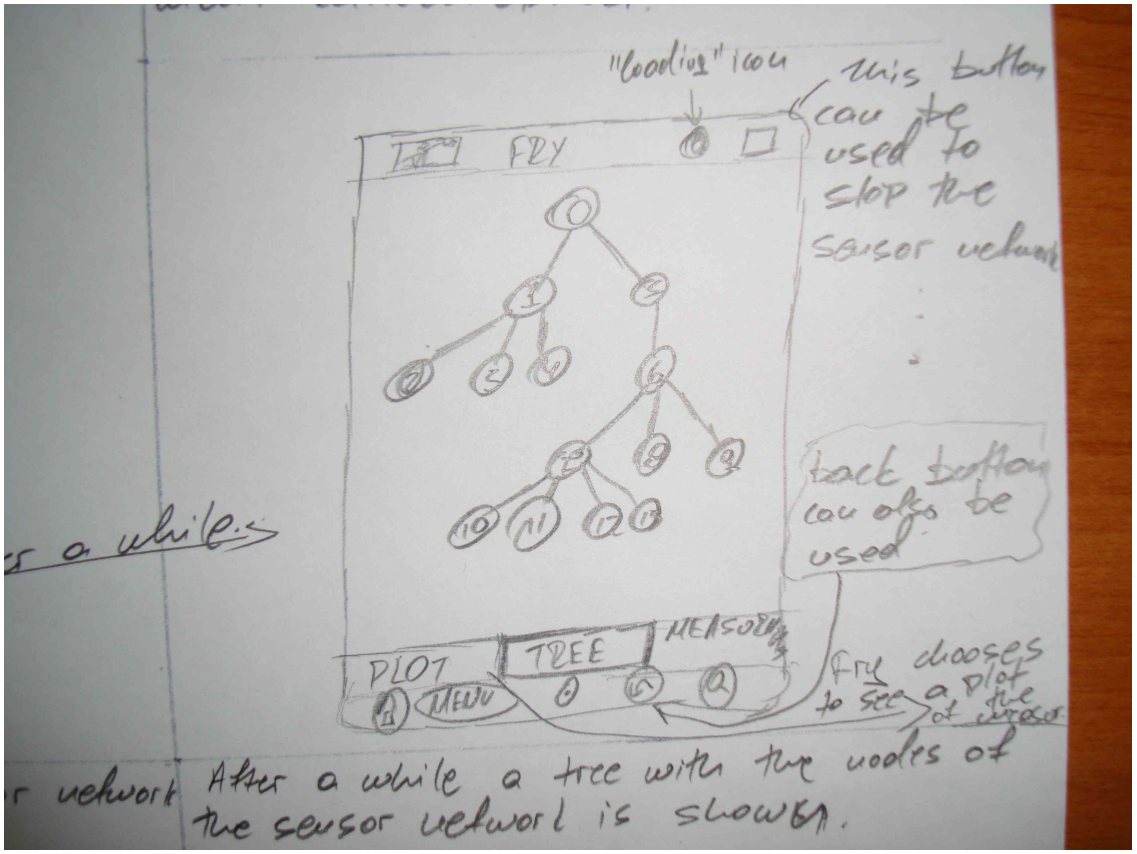

FIGURE 3.5: *Storyboarding 2nd Image.*

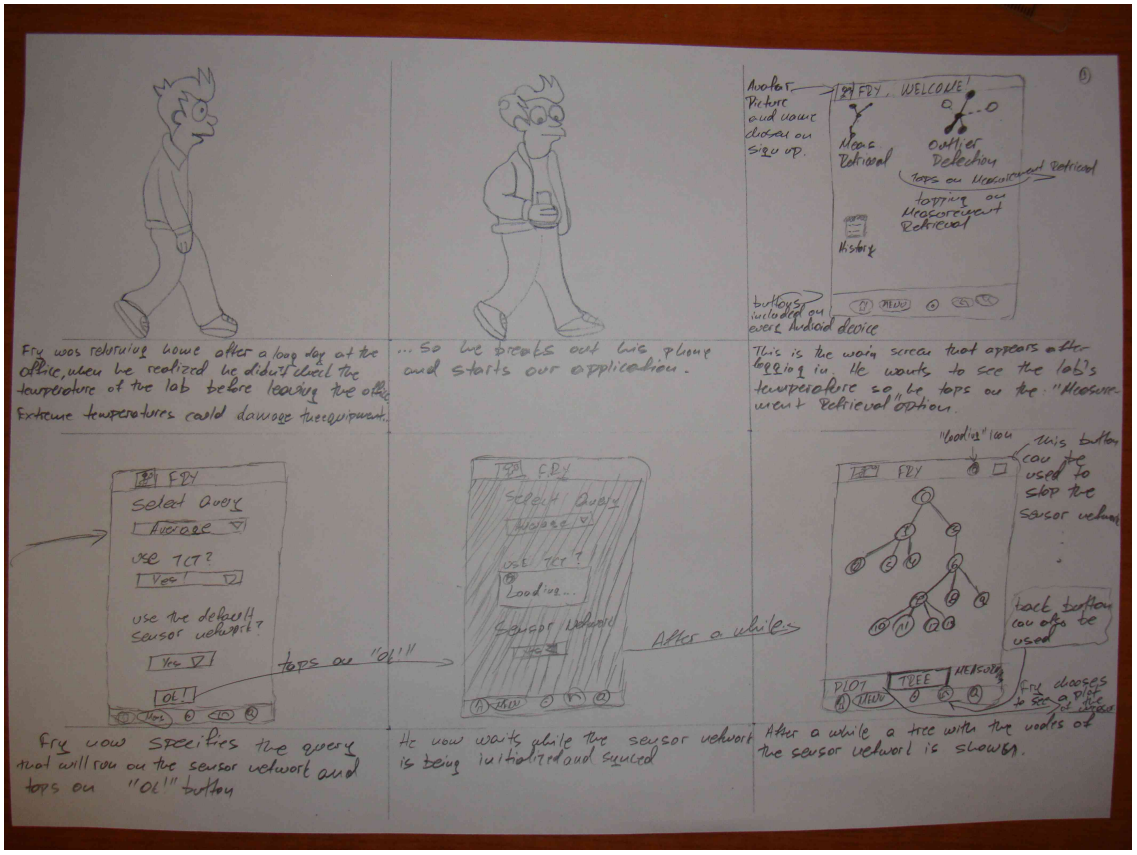

FIGURE 3.6: *Storyboarding 3rd Image.*

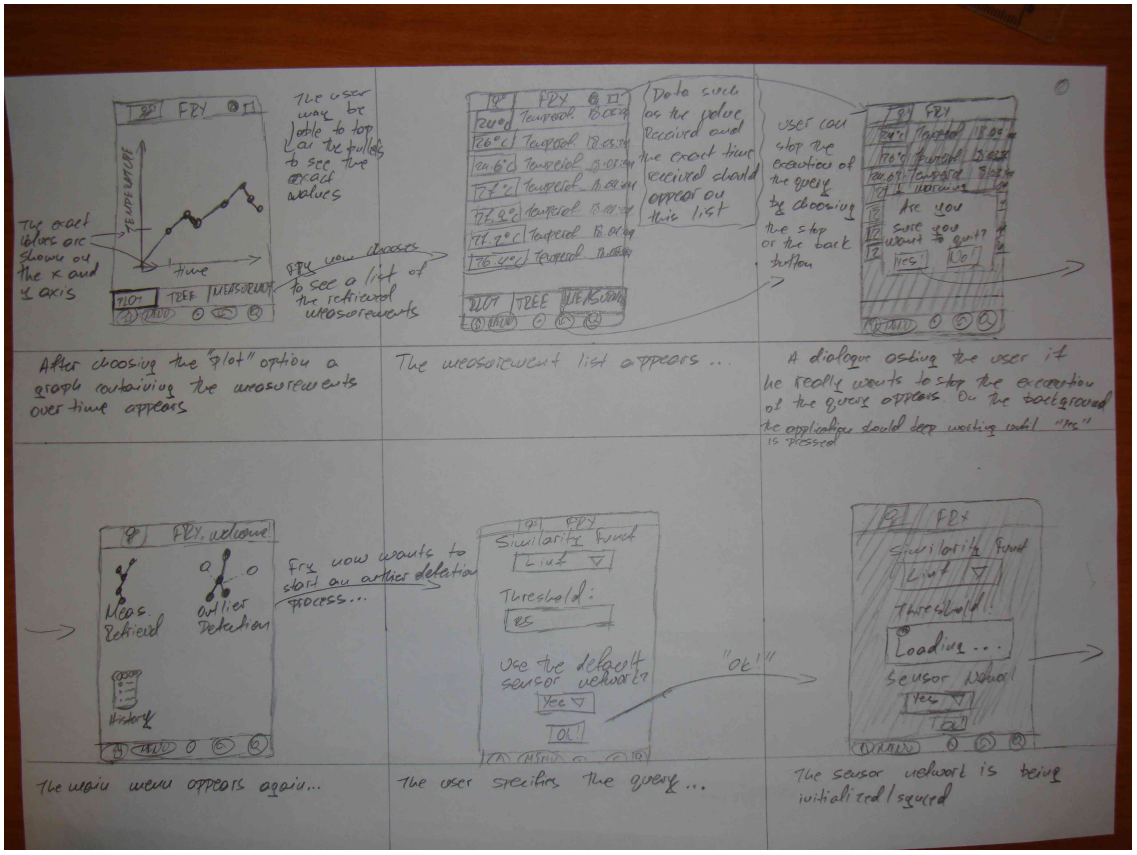

FIGURE 3.7: *Storyboarding 4th Image.*

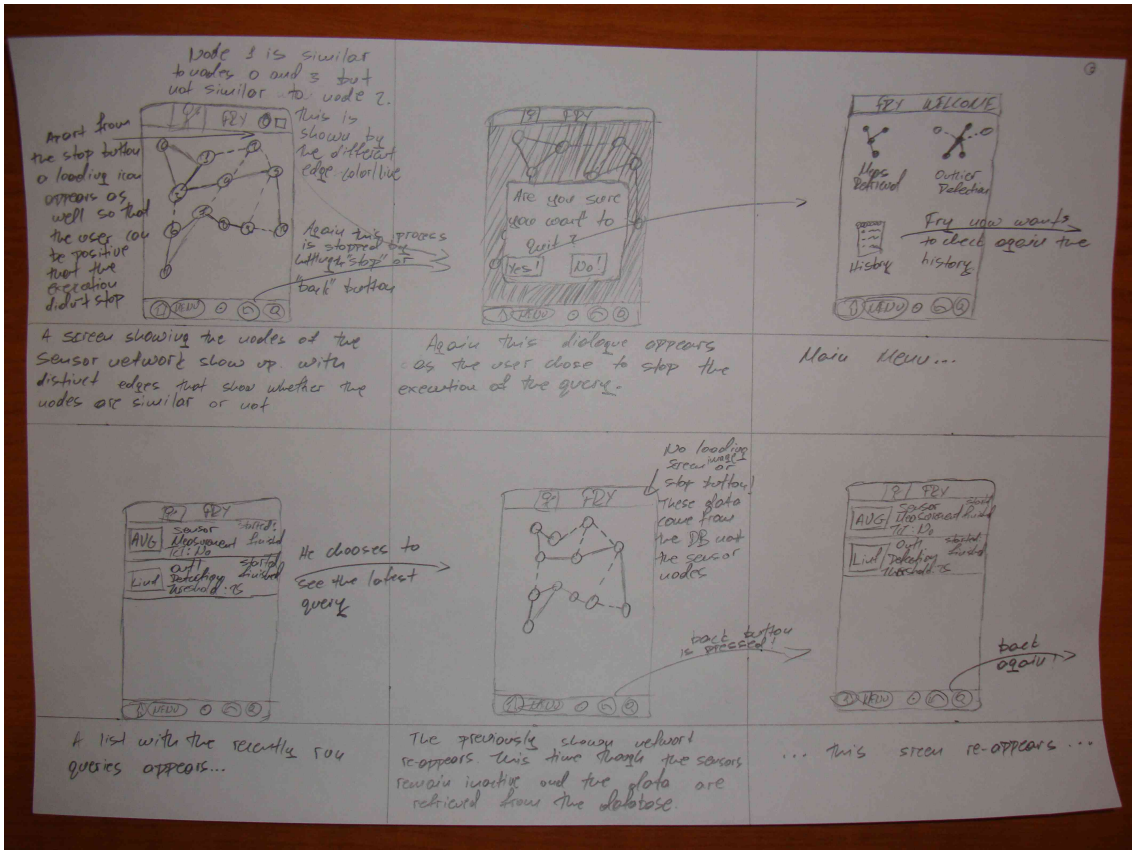

FIGURE 3.8: *Storyboarding 5th Image.*

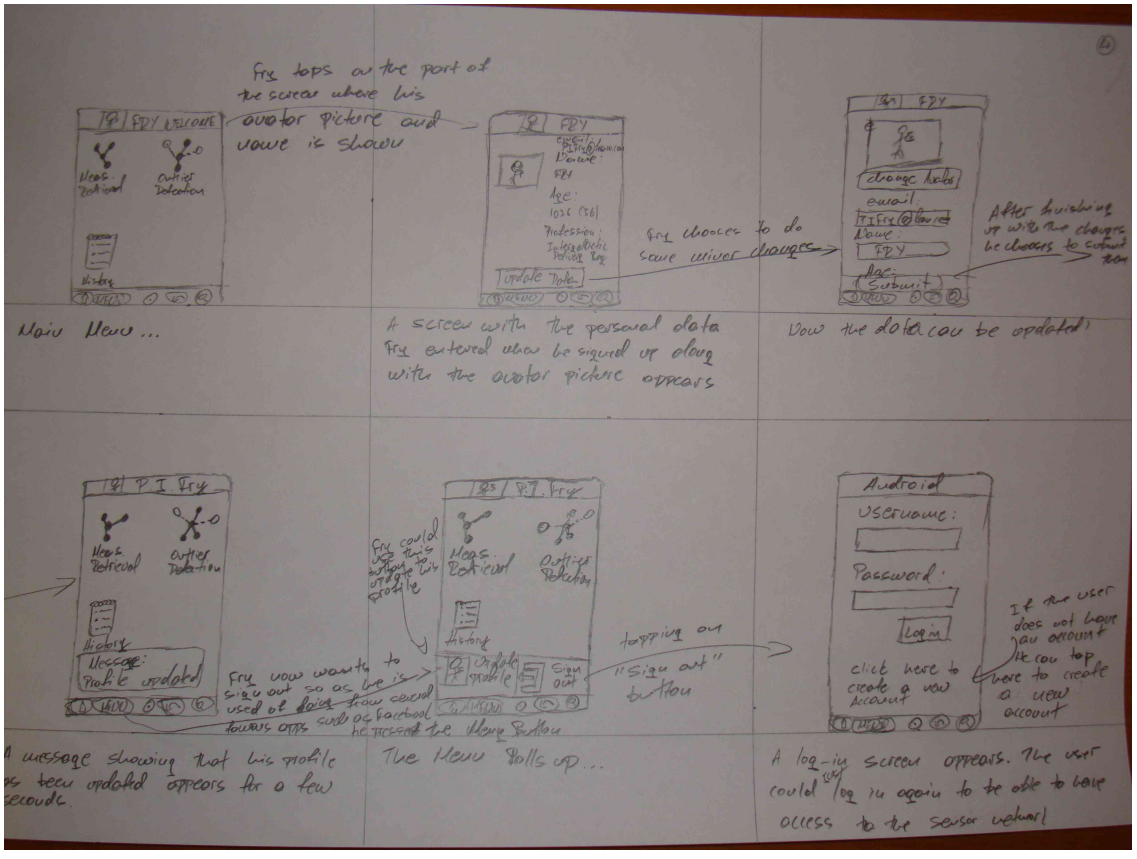

FIGURE 3.9: *Storyboarding 6th Image.*

These illustrations show some simple screens of the application. As mentioned they are the first step towards the final user interface of the program. Once this step is completed it is easier to get in contact with end users and find out if the UI of the application is understandable or if improvements should be made.

3.3.1 Receiving Feedback

After showing these images to potential users we were able to collect feedback that would allow us to make the interface better. At first glance, the users noticed that the interface seemed to be similar to other well-known applications such as Facebook, Google Plus and others. This was intentional and it is undoubtedly a positive feedback. By using a familiar interface the user spends less time familiarizing himself with it and more time actually using it.

The users faced some problems considering the terminology used. For example when the user chooses the option: "Measurement Retrieval" a screen appears that contains the term: "TCT" this is because the program that operates on the sensor network implements TiNa, a scheme used to minimize energy consumption. While it is critical to make sure that no misconceptions exist from the user, this fix has a low priority as the users will be informed about the various operations of the system, when it is delivered to them. An easy fix, however, would be to include a button next to it. This button when clicked on, it could show information or even examples of how this function could be used.

On the other hand, some of the users expressed concerns about the fact that it may be difficult for them to spot a more "secret" link. Specifically, the storyboards show that by taping on the top of the screen, where the user's name and avatar picture is displayed, they could have access to a screen that includes all the personal data given by them when singing up. This has certainly a higher priority and it will be fixed on the next stage.

Overall, this stage was successful, it appears that the interface will be familiar to the users but some minor changes should be implemented to make it even better. These changes will be viewed on the next stage, which is the paper prototyping.

3.4 Paper Prototyping

Paper prototyping is a widely used method in Human-Computer Interaction. It provides the opportunity to create software that meets the user's expectations. During this stage, again, hand-sketched or computer made drawings of the interface are created, but these prototypes are usually more detailed when compared to the ones created during the storyboarding phase.

The main idea is the same; developers use this technique to test the interface they have in mind, using real life users, without writing a single line of code. While paper prototypes are usually more detailed, as it can be observed from the following images, it certainly requires far less time to create, compared to the time that would be needed if the entire user interface was implemented programmatically, and thus it is easier to make changes.

Usually, during this stage simple office supplies are used once again like pen and paper. Since in our case we try to create the user interface of a mobile device, the paper prototypes should look like mobile phones. Thankfully, it was not necessary to draw multiple instances of the layout of a mobile phone, because a simple layout was found online and was used instead. This helped us focus on the actual UI design without wasting too much time creating a drawing of a mobile device.

FIGURE 3.10: *Paper Prototyping 1st Image.*

3.5 Testing, Evaluation & Adjustments

There are various ways to evaluate the user interface of an application from Heuristic Evaluation, to Hallway Testing and more. In this specific project Cognitive Walkthrough along with Think-Aloud Methodology was used.

3.5.1 Cognitive Walkthrough

Cognitive Walkthrough is a way of testing a software and identifying usability issues. It starts by specifying the set of actions necessary to accomplish a specific task and the way the system responds when every single one is performed. Later the designers and developers use a group of potential users and they ask them to perform the specific tasks. Afterwards a report of issues is compiled based on the completion or incompletion of the specified tasks.

There is a number of questions that the evaluating team should ask while deciding if the execution of a specific task was successful or not. Some of them are the following:

- Is it easy for the user navigate correctly in order to reach his goal?
- Can the user notice the state the application is on at all times?
- Is every button easy to spot by the user?
- Is the feedback provided by the application enough to make the user feel comfortable that he is following the right path?
- Is the user able to complete a specific task in a reasonable time window?

Below is the list of tasks that the users were requested to complete along with the time window in which the are supposed to complete the specific task:

I Supposedly that the user has already created an account with the specified username and password, we want him/her to use them in order to log into the system. (6 seconds including the transitions of switching the paper prototypes)

II Change the Avatar picture and the first name he chose when he/she created the account. (13 seconds)

III View the last query he/she executed on the sensor network. (10 seconds)

IV Run an outlier detection query on the sensor network using L inf as the similarity function and a threshold of 50. (15 seconds)

V Stop the execution of the query. (2 seconds)

VI Execution of a sensor measurement query. Select to NOT take into consideration the TCT and and to show the average of the measurements. (18 seconds)

VII View the plot of the measurements, the tree structure created by the sensor network and the list containing each measurement. (8 seconds)

VIII Stop the query. (2 seconds)

IX Log out. (4 seconds)

Below is a table with the expected time for each task along with the time the users needed in order to complete it.

Task	Expected Time	Anne	John	Katia
I	7	5	5	4
II	19	12	17	7
III	9	4	6	3
IV	15	8	14	7
V	3	1	4	1
VI	18	6	13	7
VII	8	3	4	2
VIII	3	1	1	1
IX	4	6	13	8

The time the users achieved was timed by a person using a conventional timer so some sort of deviation is expected. Additionally, since the users were talking while performing the tasks (the reason will be mentioned later) in some occasions we had to roughly subtract that time so the values may not be that precise. Nevertheless, the green values show that a user had no problem performing the task within the time limit whereas the red values show that he faced a problem.

At this moment we should say a couple of things about the users. Firstly, Anne is a professor with experience in software systems. She uses mobile devices every day, so she is expected to do well on these tasks, and so she does. Katia, is a young student and as every 23 year-old she uses computers and smartphones all the time. As a result, if something is wrong in the design it will surely be spotted by those two users. John is significantly older than the rest of the group, and while he uses his smartphone on

an everyday basis, he is expected to face some problems. All these users are expected to complete every task, but some latency on behalf of John is also excepted and the numbers collected confirm this hypothesis.

3.5.2 Think Aloud Method/Protocol

Think-aloud protocol is a method used in usability testing. The main purpose of this method is to collect as much data as possible from users concerning the design of the application. During this process users are encouraged to express their thoughts while they try to complete a specific task. In our case, the tasks that the users were supposed to complete are ones mentioned earlier. The paper prototypes created earlier were also used for this process.

This method enables the observers to see first-handed the difficulties users might have while using the application. Additionally, since the users are not guided but they are encouraged to express their thoughts, the observers can have at all times a direct access to the user's state of mind. Usually, this process is recorded, but due to the limited resources the user's thoughts were just being noted and a discussion took place later to expand their thinking, explain what they meant when making a comment and so forth.

3.5.3 Adjustments

At the end of this process we were able to notice that logging out and stopping the execution of a query were certainly problematic. Stopping query was supposed to occur by pressing a stop icon at the top of the screen. Since John was not able to spot it, we decided to make it bigger and to add more buttons that would be responsible for the navigation and for special functionality on the top of the screen. Furthermore, next to this button a "loading" icon will be added to let the user know that this query is currently being executed. The action bar as it is commonly known is used by many well-known applications for this specific purpose. This is a bar that stays on the top of the screen at all times. Even if the user scrolls down a list this remains visible. Additionally, since the back button is used in Android devices to stop a function or go back a similar functionality should be supported by this application. To sum up, the user can now stop the execution of a query by pressing a stop button which stays at the top of the screen at all times or by pressing the back button on the device.

During this testing procedure it was obvious that some adjustments should be performed concerning the "log out" functionality. The user was supposed to press the menu button and select the log out icon. While this is quite common among Android devices (this is

the way a user can log out of Facebook on an Android device) we thought it would be much better to relocate this button. Additionally, after searching on the official Android Developers website, an article was found that stated exactly what we discovered by ourselves. The options that appear when a user presses the menu button are rarely used. The reason is of course that they remain invisible during the greatest part so the user does not even realize their existence. It is also stated that developers are advised to stop using this functionality as it will not be supported on later versions. Since the action bar will be used for this kind of functionality, therefore we thought it would be better to add the log out button on the action bar as well.

Chapter 4

Sensor Network & TinyOS

4.1 Introduction

TinyOS is a free open source operating system. It is written in nesC programming language, which is a dialect of C optimized for the low memory usage of sensor devices. TinyOS programs form components. A component can use and can be used by other components. Interfaces are used to enable the interconnection of the components.

Certain interfaces are provided by TinyOS "out of the box". These modules usually support basic operations such as packet communications, storage, timers and so forth. Additionally, the motes can interact with computers to print messages on the terminal or to send messages to the serial port by using the TinyOS API and implementing the appropriate methods.

TinyOS provides a great framework which in turn is responsible for great applications. These applications range from simple programs that have as a main purpose to help programmers understand how things work, up to complicated programs that implement non-trivial complex applications described in research papers.

4.2 Developing a TinyOS Application

Before a programmer starts implementing a program in TinyOS, he should take some time to review some of the tutorials available online. The vast majority of these tutorials use the aforementioned sample programs to teach the potential TinyOS programmers everything about this system with a step-by-step procedure. Additionally, "TinyOS Programming" [8] is a great book that will certainly be useful not only to a beginner in TinyOS but to more experienced programmers as well.

FIGURE 4.1: *Iris mote.*

What is more Yeti [3] is a plugin for eclipse IDE that can be very useful while development tinyOS applications. Although it is not currently under development, it is a tool that undoubtedly will save a lot of time to any programmer. Additionally, a syntax highlighter for nesc is available for the famous editors gEdit and Kate.

4.2.1 Simulating TinyOS Networks

TinyOS applications are expected to run on motes with very limited resources in extremely uncontrollable physical environments. If that was not enough the embedded nature of those sensors makes controllable experiments difficult, therefore reproducing a bug is virtually impossible. As a result debugging is a really difficult procedure.

What adds to that statement, is the fact that no mechanism can be used to control the execution of the program. No breakpoints can be used to check if the program runs correctly and printing out messages can be truly problematic as the buffer is very limited and messages are frequently lost. Not to mention that in order for these messages to be printed on the screen of a conventional computer, every mote has to be connected with it. However connecting the motes an entire sensor network to a PC can be extremely inconvenient.

TOSSIM is a very useful mote simulator that can be used to easily develop sensor network applications. This simulator scales to thousands of nodes and compiles directly from the source code. TOSSIM simulates the TinyOS network stack at the bit level, this means that the programmer can use this simulator to experiment not just with top level applications but with low level protocols as well.

Below is a sample of the python script that enabled us to simulate the nesC application.

```
#!/usr/bin/python

# import TOSSIM simulator
from TOSSIM import *
import sys ,os
import random

# these are the messages used during the transactions
# between the base station and the server

from ForwardToParentMsgAvg import *
from NotifyParentMsg import *
from RoutingMsg import *

t=Tossim([])
h=sys.stdout

# output everything to logfile.txt

f= open('./logfile.txt','w')
SIM_END_TIME= 10000 * t.ticksPerSecond()

# these are the channels used, more information
# considering this feature will follow...

t.addChannel("childPrblm",f)
t.addChannel("RoutingMsg",f)
t.addChannel("NotifyParentMsg",f)
t.addChannel("myTimer", f)
t.addChannel("myCount",f)
t.addChannel("myLed",f)
t.addChannel("Serial",f)
t.addChannel("windowStream",f)
t.addChannel("SRTreeC",f)

# TOSSIM enables us to select exactly when
# the motes will boot.
```

```
38
39 for i in range(0,10):
40     m=t.getNode(i)
41     m.bootAtTime(10*t.ticksPerSecond() + i)
42
43 # This file describes the topology of the network
44 # specifically it includes couples of nodes
45 # for each couple an one-way edge is created
46 # for a two-way edge both the same couple must
47 # be added with a reverse order
48
49 topo = open("topology.txt", "r")
50
51 # ...
```

Listing 4.1: Python script making use of TOSSIM simulator

The channels added on the code above are responsible for printing out debugging messages at run-time. This is how debugging messages can be printed:

```
dbg("SRTreeC" , "Forwarding NotifyParentMsg from senderID= %d
to parentID=%d \n" , m->senderID, parentID);
```

It is identical to the way fprintf works in C but these commands are omitted if the application is installed on conventional motes in order to run faster.

To interact with the simulated network SerialForwarder can be used. This interface enables its user to send and receive data through the serial port. Additionally, Message Interface Generator (MIG) can be used to generate Java classes or python scripts that represent the message objects.

Below is the make file with the commands used to generate these files for 3 distinct message packets.

```
1 MyCodeFromLab.class: $(wildcard *.java) RoutingMsg.java
2 ForwardToParentMsgAvg.java NotifyParentMsg.java
3     javac *.java
4
5 RoutingMsg.java:
6     mig java -target=null $(CFLAGS)
7     -java-classname=RoutingMsg
```

```
8       SimpleRoutingTree.h RoutingMsg -o $@
9
10  RoutingMsg.py:
11      mig python -target=null $(CFLAGS)
12      -python-classname=RoutingMsg
13      SimpleRoutingTree.h RoutingMsg -o $@
14
15
16
17  NotifyParentMsg.java:
18      mig java -target=null $(CFLAGS)
19      -java-classname=NotifyParentMsg
20      SimpleRoutingTree.h NotifyParentMsg -o $@
21
22  NotifyParentMsg.py:
23      mig python -target=null $(CFLAGS)
24      -python-classname=NotifyParentMsg
25      SimpleRoutingTree.h NotifyParentMsg -o $@
26
27
28
29  ForwardToParentMsgAvg.java:
30      mig java -target=null $(CFLAGS)
31      -java-classname=ForwardToParentMsgAvg

TOSSIM proved to be more than helpful during the developing phase. Unfortunately, even if everything runs smoothly on TOSSIM, when the same program is installed on sensor motes some bugs may still appear. At this point the only identifiers that can be used from the programmer to solve these bugs are the LEDs included on the sensor

nodes. This is perhaps the most difficult part of the TinyOS application. A simple bug may end up taking way too much time to solve, so methodical programmers may have a certain advantage at this point.

4.3 Power Consumption

Since these motes are supposed to run independently in remote areas for a long time they should be energy efficient. Limiting power consumption has been the main purpose of many publications in the field of Wireless Sensor Networks this definitely shows the importance of energy efficiency on such networks. Certain mechanisms were used to limit the power consumption in this application as well.

Firstly, it should be mentioned that there are two ways to accomplish energy efficient algorithms. The first one is by limiting the information transmitted by individual nodes and the second one is by increasing the amount of time the nodes remain inactive.

Both of these ways were used to make our application more energy efficient. Two algorithms were used to accomplish this, TAG and TiNA.

4.4 TAG (Tiny AGgregation Service for Ad-Hoc Sensor Networks)

TAG [9] (Tiny AGgregation Service for Ad-Hoc Sensor Networks) among others, states that the processing and computation of aggregate queries can be performed within the network to limit the transmitted amount of data. In TAG the base-station generates an aggregate query that the user specifies and it is being transmitted towards the sensor motes within the network.

Messages are transmitted from the base station to the nearest nodes and these messages are forwarded to their neighborhood nodes, thus creating a tree. At the end of this distribution phase, a tree is being created and the base station is positioned at the root of this tree while each node belongs to a certain depth and has a unique ID. Additionally, each node is aware of the parent node to whom it will be periodically sending the outcome of the aggregate query computed by the measurement it receives along with the measurement received from the sub-tree formed under it.

Furthermore, each node is aware of the epoch, which is the time window in which new measurements are being retrieved. This epoch is divided in shorter time slots during which the nodes at a specific depth operate. Within this time slot, a node has to firstly

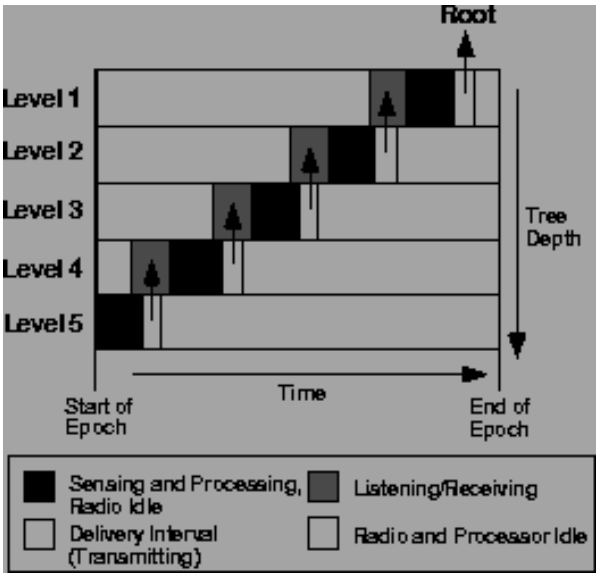

FIGURE 4.2: *Epochs of nodes that belong to different depths.*

retrieve the measurements of his children, include its own measurement and forward a message including these data to the parent node. The nodes that belong to other depths remain inactive during this procedure until the time comes for them to operate accordingly. This is known as the collection phase.

It should be mentioned that the radio of a node remains inactive during the greatest part of the epoch. This is the reason why the power consumption is significantly lower when compared to a system that does not implement a similar mechanism.

A valid question at this point would be how a node can choose the time slot during which the radio remains active. The time window has to be long enough in order to receive all the messages from the children nodes, but not so long that the epoch ends before all the messages of the current epoch are retrieved from the base station. There is certainly no right answer to this question, it depends on the tree that is formed on each occasion. However it should be clear that if the epoch is too small and the tree too long, then the window during which the messages are transmitted may be too small and some of them may be lost.

Another point that should be clear from the figure 4.2 is that the time slots are not exactly sequential. Parents do not start listening at the exact time when their children send their data, this is because certain limitations exist in the quality of the clock synchronization algorithms. As a result, parents are supposed to listen before the children start sending their data.

4.5 TiNA (A Scheme for Temporal Coherency-Aware in-Network Aggregation)

TiNA [12] was also used to limit the power consumption. The main idea of this publication is that two sequential measurements retrieved by a sensor usually are not that different from one another. As a result sending sequential values that are very similar does not significantly change the result of the aggregate query of the sensor network. However it does result in higher power consumption since identical values are sent periodically. Therefore, a tolerance clause can be used to avoid sending the same value over and over again. If the newer value is different enough from the last one it is being transmitted, otherwise it is not.

This mechanism lowers the number of messages that are being transmitted within a network since new measurements that do not provide any useful information are withheld. Since sensor network applications are intended to run on different environments, some measurements that are considered useful in one occasion may not be so useful in another. Therefore, the user is able to select which measurements are in fact useful and which are not by specifying the tolerance clause at the beginning of the application.

This tolerance is described by the TCT. If the previously sent value is different from the current more than TCT% then the current value is also sent otherwise it is being suppressed.

$$\frac{|Vnew - Vold|}{|Vold|} > TCT\%$$

4.6 Description of Sensor Measurement TinyOS Application

This thesis implementation contains two TinyOS applications. The first one is used to collect the aggregate values of the sensor network. The main object of this application is to retrieve the measurements of the network and use the serial communication mentioned earlier to transmit these measurements to a server. That way the measurements can be stored into a database and can be later retrieved from the mobile application.

4.6.1 Routing Phase

At first this application begins with the routing phase. During this phase a message is broadcasted by the base-station and is being forwarded from node to node until an

entire tree is formed. This message contains information about the aggregate query that is going to be executed and it includes data about the current depth and the parent node.

```
1  typedef nx_struct RoutingMsg
2  {
3      // The ID of the mote sending the routing message
4      nx_uint16_t senderID;
5
6      // The depth of the sender of this message
7      nx_uint8_t depth;
8
9      // The aggregate query that will be executed
10     // This can be summary, max-min value etc.
11     nx_uint16_t cosummaryFun;
12
13     // At this point the TCT is specified.
14     nx_uint16_t tct;
15     nx_uint8_t ignoreTCT;
16 } RoutingMsg;
```

Listing 4.3: Struct used to contain the fields of the Routing Message

When a node receives a routing message, it uses the data included in the message to set up the local variables used during the collection phase and it responds with a message notifying previous node that from now on it is considered as the current node's father. The parents from now on are aware of which nodes are their children so during each epoch they know how many messages they should expect to receive. If a parent node does not receive a packet from a child it is considered that its value has been suppressed due to the TCT.

In general, lost messages are quite common on real life sensor networks due to various reasons. Mainly messages can get lost because of collisions between two or more packets. The same thing applies to our sensor network. Routing and NotifyParent messages can get lost. Re-sending routing messages can cause more problems than it would solve so no special actions are performed when a routing message gets lost, but a simple restart of the application would solve this problem. On the other hand when NotifyParent messages are lost a node is unaware that an entire sub-tree may exist under it. As a result the aggregate query may be complete wrong if the values of that branch are omitted. A certain mechanism is implemented that uses the unique id of a node to decide when the notify parent message will be sent, that way we can avoid losing messages from

collisions. Additionally, when a message with a measurement arrives and the sender is not on the list with the children nodes, it is instantly added to avoid any problems.

4.6.2 Synchronization Phase

As mentioned above each node turns on and off the radio on specific time slots to receive and send packets. In order for this to happen every node on this network has to be synchronized. A special component is used for this purpose that makes use of a global clock. After syncing every node can estimate the exact moment to turn the radio on and off.

```
components TimeSyncC as SyncC;
MainC.SoftwareInit -> SyncC;
SyncC.Boot -> MainC;
SRTreeC.SyncControl->SyncC;
SRTreeC.GlobalTime->SyncC;
```

Listing 4.4: Wiring of Time Sync Component

```
// ...
// The synctimer component should be booted by now
uint32_t tmpTime, stime;
// if this is equal to SUCCESS this node is synced
if (call GlobalTime.getGlobalTime(&tmpTime)==SUCCESS)
{
    // counter to keep count of how
    // many times this node is
    // is considered synced
    timesSynced = timesSynced+1;
    if(timesSynced >= 5){
        // if period is 10000 miliseconds
        stime= (tmpTime+10000)/ 10000;
        stime-=1;
        stime*=10000;
        call GlobalTime.global2Local(&stime);

        // call the appropriate timers to turn on and off
        // the radio
        call TurnOnRdioTimr.startPeriodicAt(stime-
        curdepth*500,4000);
```

```
22          call TurnOffRdioTimr.startPeriodicAt(stime-
23          (curdepth+1)*500-smltnWnd,4000);
24
25          // it is synced stop syncing
26          call SyncControl.stop();
27      }
28  }
29  else
30  {
31  // if it gets here this node is not synchronized
32  // act accordingly
33  }
34  // ...
```

Listing 4.5: Using Time Synced component

4.6.3 Collection Phase

After the motes have been synced they are ready to collect measurements and calculate the result of the aggregate query. The aggregate query demands the calculation of the summary, average, maximum, minimum or count value of the tree. This process is performed periodically until the user selects to stop the measurement gathering. The result of the aggregate query is sent to the base station and is being forwarded through the serial port. On the receiving end of this serial port there is a web service listening for new packets. When a new packet is received it is un-serialized and stored into the database.

4.6.4 Ending Phase

If the user selects to stop the execution of a query the motes have to be informed. However since the motes turn on and off the radio if such decision is made by the user and a cancellation query is sent there is no guarantee that it will reach every node. In order to be certain that no problems will occur while stopping the query a special window is opened periodically. During this window every node on the tree turns on the radio. If the user desires to stop the execution, a special message will be transmitted through the nodes of the tree. After receiving such a packet every mote re-initializes its variables, the timers are stopped and the radio is turned on. That way when the user decides to execute another aggregate query every mote will be in his disposal again.

If on the other hand such a query is not transmitted this window shuts down and the sensor network goes again in the collection phase, until the next epoch.

4.7 Outlier Detection

The second application is about outlier detection. This is the process of detecting abnormal node measurements within a sensor network. This information is useful since it may lead to interesting findings. Abnormal measurements may be due to malfunctioning motes or due to other physical phenomena, such as fires. This application was created by Mr. Antonis Igglezakis as a part of his thesis implementation and was included in this project. The implementation was based on a recent paper from Mr. Sabbas Burdakis about an algorithm for detecting outliers in sensor networks, based on a geometric approach [2].

4.7.1 The Geometric Approach

This outlier detection framework is based on the geometric approach [2]. This approach enables us to monitor whether a specific complex function computed over the average of vectors maintained by all sensor nodes, is above or below a certain threshold. Many functions can be used to determine whether two nodes are similar or not, but since it is not this thesis' subject we will not continue describing the various details of this approach.

The only thing that we need to specify at this moment is how this application interacts with our system. It can be viewed, typically, as a black box that uses the user's inputs and produces the output. The user specifies which similarity function will be used and which is the threshold. Each edge gains a similarity number, this number can be above or below the threshold provided by the user and therefore the two connected edges can be similar or dissimilar.

4.8 Summary

This thesis project includes among others, two TinyOS applications. The first one is a simple measurement retrieval application, that utilizes the user's input to perform the execution of a sum, average, maximum, minimum or count query. Additionally, this application includes a couple of mechanisms to limit the power consumption of the sensor motes in order to expand their battery life.

The first mechanism is to turn the radio on only when it is absolutely necessary. Radio can drain the battery life within a short period of time so it is advised to use it wisely. The radio turns on, only when a node is supposed to receive packets from its children and transmit a packet to its father node. In all other occasions the radio remains off.

TiNA [12] was also implemented. Since sending and receiving measurements that are not so different from previous ones, also drains the battery life and no useful information is being transmitted, this protocol puts an end to this. Measurements are being transmitted only if they are different enough from previous ones. Which measurements are considered different and which are not is up to the user of this application.The user on the beginning, specifies the tolerance clause by setting up the TCT. If the newest value is more than TCT% different from the previously sent one, it is considered different enough and it is being transmitted.

When the user wants to stop the execution of this application, a cancellation query is being transmitted. Since the radio of the nodes in a network is being turned on and off on completely different time slots, arbitrarily broadcasting a packet on a random time slot would definitely result in its loss. So on a specific time slot every node of the network turns on the radio for a limited time. If the user has chosen to stop the execution of this query a packet is broadcasted at that specific time and it is received from the nodes of the entire network.

Apart from this TinyOS application an other one responsible for detecting outliers is also included in this thesis implementation. Outlier detection is the process of detecting nodes with abnormal measurements within a network. Methodologies related to this process have gained the attention of the academic and industrial community due to the interesting information that can be extracted from such findings.

Since the TinyOS application performing the outlier detection technique was already implemented by another student for his thesis implementation, we just included it in this project. A client and a server were implemented to correctly control this application and enable the user to detect and view dissimilar nodes within a network.

Chapter 5

Web Service

5.1 Introduction

The main objective of this thesis implementation is to be able to control the described sensor network via a mobile device from any place in the world. In order to accomplish that an intermediate layer had to be used since the sensor network cannot directly connect with the mobile device. The reason why this step was necessary is because no web service is bundled with the TinyOS architecture, so we had to build our own.

This intermediate level has to accept connections from the mobile device through the internet and interact with the sensor network to manipulate it. Apart from that this level has to be able to receive the messages from the sensor network through the serial port, store them in a database and send those data to the client as well.

5.2 Choosing the Right Architecture & Framework

Recently, a lot of work has been done in the field of Web Services, mainly due to the industrial interest in this field. This naturally results in the creation of many distinct architectures and frameworks. One of the most challenging parts of the engineer's job is to choose the tools that will enable him to create the best application possible. Since in this case Web Service tools are rolled out almost daily, choosing the right ones for a specific task can be a really tough task.

SOAP (Simple Object Access Protocol) and REST (REpresentational State Transfer) are the two approaches available in this field. Each of these two architectures has a series of available frameworks and tools that can be used. Every single one of these architectures and respectively their frameworks and tools have their own advantages

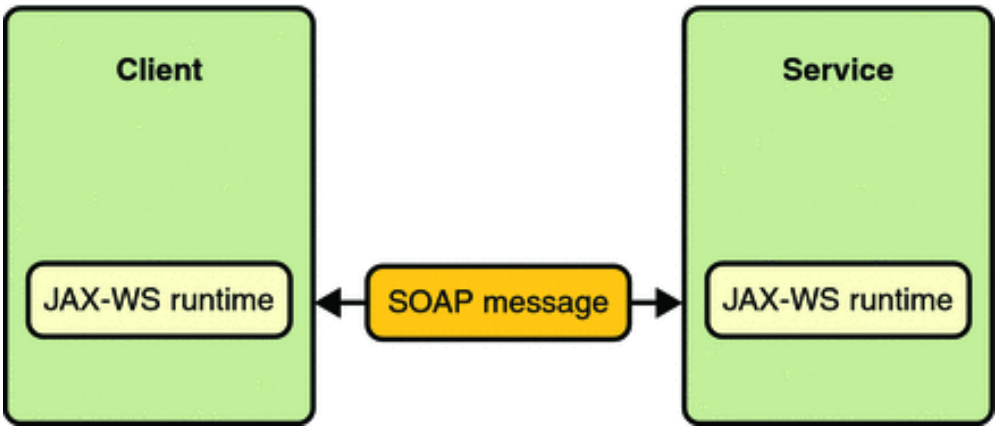

FIGURE 5.1: *JAX-WS communication between the server & the client.*

and disadvantages so the best option depends on the occasion in which they will be used.

REST approach is praised for its ease of use and the fact that it is extremely lightweight. It has recently been used by many well-known companies and organizations. This approach is very easy to understand and it can be used by virtually any client and server that has HTTP/HTTPS support. SOAP on the other hand has been used extensively for the past few years and it will continue to do so. The majority of the initial issues have been fixed since it has been around for quite a while.

SOAP has some additional overhead compared to REST, but it also comes with some advantages over it. SOAP is more "generic" than REST which means that while REST architecture can only be used on HTTP/HTTPS protocols, SOAP can additionally be used over SMTP (Simple Mail Transfer Protocol), JMS (Java Messaging Service) and more. On the other hand SOAP relies on XML to represent the transmitted information which is more verbose compared to REST. After weighting each option we decided to go with SOAP Architecture as we noted in the section: "REST vs SOAP"

5.3 JAX-WS

JAX-WS stands for Java API for XML Web Services. JAX-WS is a framework used to build web services and clients that communicate using XML. Although SOAP message transaction can be very complex, this API hides this complexity from the developer.

In JAX-WS, the developer specifies the web service operations by defining the available methods. Annotations are used to specify the various elements of the Web Service. Client programs are also easy to code. A client creates a proxy (a local object representing

the service) and then simply invokes methods on this proxy. These are called stubs and the corresponding methods of the service are called skeletons. With JAX-WS, the developer does not generate or parse SOAP messages. It is the JAX-WS runtime system that converts the API calls and responses to and from SOAP messages.

```
1  // Imports
2  // ...
3  import javax.jws.WebService;
4  import javax.jws.WebMethod;
5  import javax.jws.WebParam;
6  // ...
7  // Name of the web service
8  @WebService(serviceName = "SensorWebService")
9  public class SensorWebService {
10     /**
11      * Web service operation
12      */
13      // Name of the method
14     @WebMethod(operationName = "startMoteNetwork")
15     public String startMoteNetwork(@WebParam(name =
16     "routingMSG") String routingMSG) {
17     androidToTiny and2Tiny = new androidToTiny();
18                 String about2Return =
19                 and2Tiny.receiveRequestForm(routingMSG);
20                 System.out.println("about to return:
21                  "+about2Return);
22                 return about2Return;
23     }
24     // ...
25     // other methods
26 }
```

Listing 5.1: Web Service source code sample showing the annotations used in JAX-WS

After specifying the methods of the Web Service, we could start implementing the business logic. In our case, several methods responsible for the interconnection of the web service with the sensor network were implemented. Additionally, in order to create a complete user interface, the user should be able to log into the system to use the

TinyOS application and view previously executed queries, several web service methods had to be implemented for this as well.

After compiling the project a WAR file is created, this is the equivalent executable file for the Web Services. This file contains the components of the Service and after being deployed to Apache Tomcat or Glassfish we can use a client to interact with it. If we open a browser and connect to the right address the following WSDL file will be displayed:

```

Listing 5.2: WSDL file of the implemented Web Service

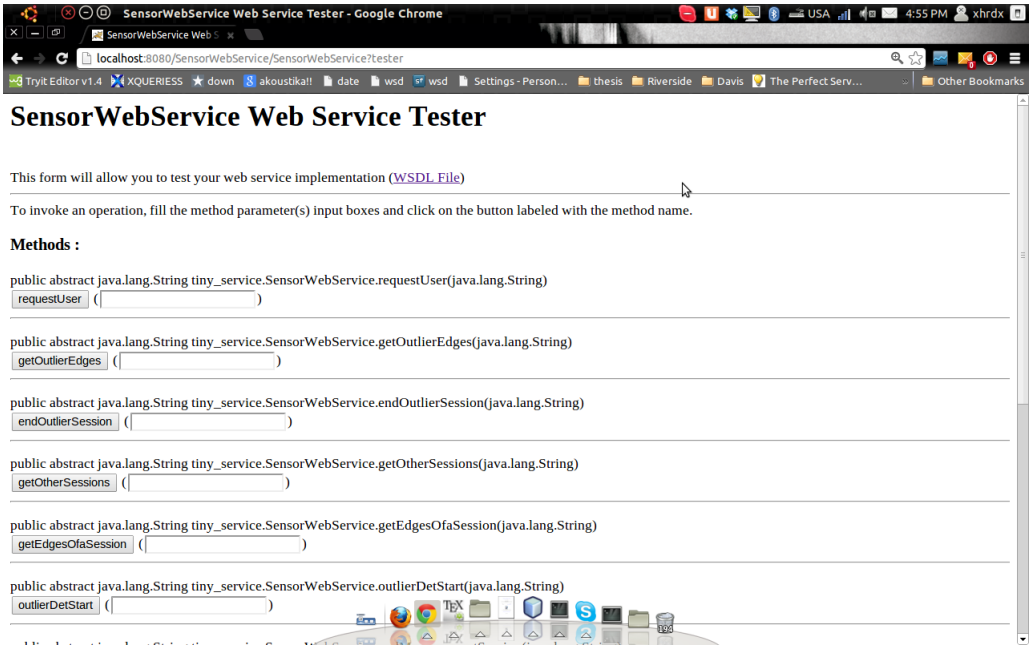

FIGURE 5.2: *Auto-generated JAX-WS web interface to interact with the Web Service*

Our service, in this example, is hosted on the URL: http://localhost:8080/SensorWebService/SensorWeb of course since this WSDL is auto-generated we can host it in a server with a different URL and the WSDL file will be updated.

Furthermore the JAX-WS Web Services once deployed, provide a simple web interface to interact with it.

5.4 XML Schema

Since the SOAP Web-Services communicate with the Clients using XML messages, we had to find a way to describe them. That way the corresponding java objects could be generated using a binder. These objects would include conventional getters and setters to bind and unbind those messages in order to manipulate their contents.

Luckily XSL (EXtensible Stylesheet Language) could be used to describe those messages and XMLBeans could be used to generate them into java objects. XSL refers to a family of languages used to render and transform XML documents. XSLT, specifically was used to describe those messages.

```
1 <?xml version="1.0" encoding="UTF-8"?>
2 <xs:schema xmlns:xs="http://www.w3.org/2001/XMLSchema"
3     xmlns:tns="http://thesis.androiny.org/measurements"
4     targetNamespace="http://thesis.androiny.org/measurements"
```

```
5      elementFormDefault="qualified">
6
7  <xs:element name="measurementList">
8   <xs:complexType>
9    <xs:sequence minOccurs="0" maxOccurs="unbounded">
10    <xs:element name="measurement" type="tns:Measurement"/>
11   </xs:sequence>
12  </xs:complexType>
13 </xs:element>
14 <xs:complexType name="Measurement">
15 <xs:sequence>
16  <xs:element name="id" type="xs:string"/>
17  <xs:element name="actualMeasurement" type="xs:string"/>
18  <xs:element name="isTemperature" type="xs:string"/>
19  <xs:element name="measurementReceivedOn" type=
20   "xs:string"/>
21  <xs:element name="sessionIDfk" type="xs:string"/>
22 </xs:sequence>
23 </xs:complexType>
24 </xs:schema>
```

Listing 5.3: XSLT file used to describe the messages containing a sensor measurement transmitted from the Web Service to the client

Later on XMLBeans was used to generate the jar files with the appropriate Objects. This gave us the ability to bind and unbind the transmitted messages automatically within the service. Apart from XMLBeans other binders could also have been used (such as JAXB). But since the differences in performance are not that noticeable XMLBeans seemed to be more than enough. These differences in the performance requirements are considered meaningless, because the service is hosted in a server with specs noticeably higher than the ones of a mobile device within the same price range, so the processing power needed from each of these binders is virtually the same.

We should clarify at this point that this method was used to bind and unbind the contents included in the SOAP messages. SOAP messages include various information about the infrastructure of the web service. But since a certain level of abstraction is implemented to avoid the unnecessary hassle, the developer interacts only with the useful information of his applications. This is why the aforementioned auto-generated objects were created to encode and decode this information.

5.5 Web Service - TinyOS Interaction

After describing the way the client-server interaction was implemented, it is time to describe how the sensor network interacts with the web service. As mentioned earlier TinyOS provides a tool that allows us to generate Java Classes and Python or C files describing the messages transmitted from the sensor motes to the computer and vise versa. This tool is named MIG (Message Interface Generator). Every message is in reality a sequence of bytes. What this tool does is parsing and un-parsing this sequence to a packet with usable fields.

Unfortunately, various problems were faced while trying to use the Java API for sending and receiving messages. Probably, many instances of the transactional mechanism were created by the web service while creating new threads to serve the requests and the TinyOS Java API could not handle that issue.

That was perhaps one of the most critical stages of this project. The provided Java API for the interconnection between the motes and the Web Service could not operate as it should. Many potential solutions were tested and every single one of them failed miserably.

That is, until we tried to implement a python script for the much needed interconnection between these two parts. Finally, that was successful. Apparently the Python API did not face any of the problems Java did. Unfortunately, it was not possible to re-implement the entire web service in python as the frameworks available for implementing SOAP services are noticeably inferior compared to JAX-WS and since the biggest part of the web service was already completed we chose to follow the middle path.

The Web Service would execute a python script which would be responsible for the communication with the sensor network. This script would remain active to receive the messages sent from the base station and store them in the database.

When the user decided to stop the execution, the client would normally connect to the web service. The web service would transmit this message to the base-station and the cancellation query would be forwarded to the nodes of the network. But, since now responsible for the communication with the sensors is not the service itself but the python script, we needed to find a way to notify the script that it is time to stop the query.

The solution was actually simple. When the python script was executed a simple file would be created. What this file represented is that a query was being executed. The python script periodically checks if this file still exists and if it does not, a cancellation

query is sent to the sensor network. As a result the only operation that was requested from the Web Service was to delete this file.

Finally, after implementing the above-mentioned system the communication between the computer and the base-station was completed.

Chapter 6

Database Design

6.1 Introduction

In this chapter, we describe the design of the database system used to support our application. This system ensures the security and the well-being of the system. It keeps

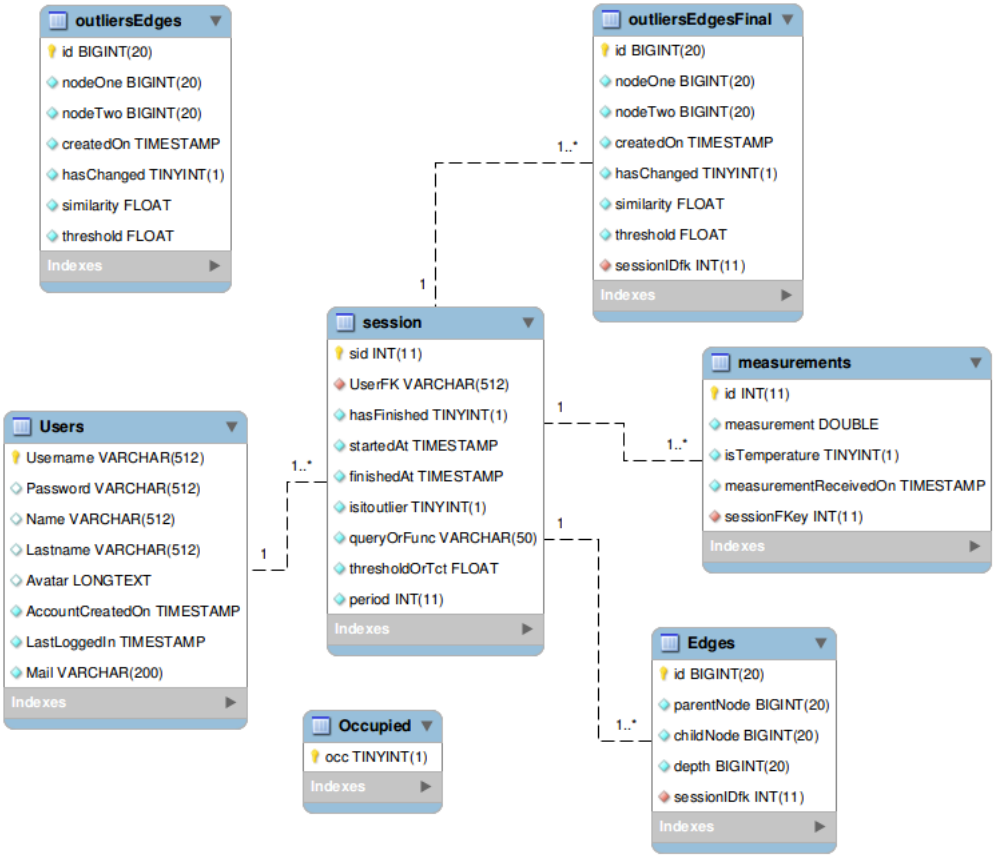

FIGURE 6.1: *Database's Enhanced Entity Relationship Model (EER).*

data that range from simple representations of objects such as the details of the users' accounts to tables storing information related to security restrictions applied to the system.

In figure 6.1 we can view the complete Enhanced Entity Relationship Model (EER) which provides a birds-view on how the database system is organized.

6.2 Analysis of the Database Design

In this section we will analyze the entities of the database system and the attributes each of these entities possesses.

6.2.1 User

The user is the actual operator of the system. No functionality can be performed if no user account has been created. The required attributes are the following:

- **Username**. It is used as the primary key of this entity
- **Password**. It is used along with the username to identify a user
- **Name**
- **Lastname**
- **Avatar**. It is an optional profile picture the user can enter
- **AccountCreatedOn**. It keeps the exact moment in which the user created the account
- **LastLoggedin**. It keeps the last time the user logged into our system
- **Mail**. It keeps the user's e-mail address. In future work this attribute can be used to send e-mails with additional features provided by the system, to restore the user's password and so forth

6.2.2 Session

The session is the central entity related to every action that takes place on the sensor network. No session can be created if the user has not logged in or signed up, since the username is used as a foreign key in this entity. This is a vital component while

executing a query on the sensor network. Every time a new query is requested, a new session is being created. The session's attributes are the following:

- **sid**. It is used as the primary key of this entity
- **UserFK**. It is used as a foreign key pointing to the user entity. Every time, a new session is created the username of the user that chose to execute the query, is stored here. The reason why this is necessary, is because we want to be able to retrieve every previously executed session along with the measurements, edges and so forth if the user chooses to see the history log
- **hasFinished**. This is a boolean attribute used to identify if the session has been completed or not. This becomes true when the user presses the stop query
- **startedAt**. It keeps the precise time in which the session started
- **finishedAt**. It keeps the precise time in which the session finished
- **isitoutlier**. This attribute is used in order to specify which application runs on the sensor network. If false, the executed application is the sensor measurement application, if true the executed application is the outlier detection app.
- **QueryOrFunc**. This attribute is used to specify the exact query or function that is being executed. If during this session the sensor measurement application is executed this field can take one of the values: sum, average, maximum, minimum or count. On the other hand, if the outlier detection application was executed it can get one of the L1, L2 or L inf options.
- **thresholdOrTct**. This is used to keep the threshold used by the outlier detection, or the TCT of the sensor measurement application. In case the sensor measurement application is executed, it gets the value "-1" if no TCT has been selected.
- **period**. This value shows how often new measurements arrive from the sensor network.

6.2.3 Measurements

In case the sensor measurement application is initialized, this entity is used to keep the retrieved measurements. The attributes of this entity are the following:

- **id**. It is used as the primary key of this entity
- **measurement**. This is the actual measurement sent from the base-station.

- **isTemperature**. It keeps information about the physical quantity that is being measured by the sensor network. The most convenient quantity is the light intensity because it allows us to easily change the retrieved measurements by just turning on and off the lights or by covering the sensor motes with another object. This quantity has been extensively used to test the application because it enables us to test the application without having to wait for a long time, as we would have, if we tested it using the room temperature, or any other physical quantity.
- **measurementReceivedOn**. This keeps the exact time in which a measurement was retrieved.
- **sessionFKey**. Foreign key pointing to the session entity.

6.2.4 Edges

When the sensor measurement application is initialized, an actual representation of the tree created on the sensor network has to be visualized on the Android application. In order for this to happen the edges created by the sensor network have to be stored in the database.The attributes of this entity are the following:

- **id**. It is used as the primary key of this entity
- **parentNode**. This keeps the id of the node that is closer to the root.
- **childNode**. This keeps the id of the node that is further away from the root.
- **depth**. This keeps the exact depth of the child node, in order to be easily visualized on the Android application.
- **sessionFKey**. Foreign key pointing to the session entity.

6.2.5 outliersEdges - outlierEdgesFinal

When the sensor outlier detection application is initialized, the sensor network has to be visualized. Apart from a simple visualization, information about the similarity of the nodes also have to appear on the client's screen. In order to achieve these visual effects this entity has to be used. Specifically, the attributes of this entity are the following:

- **id**. It is used as the primary key of this entity
- **nodeOne**. This keeps the id of the first node.

- **nodeTwo**. This keeps the id of the second node.
- **createdOn**. This keeps the exact moment when this edge arrived at the web service from the base-station.
- **hasChanged**. This keeps information about changes that occur on the edges.
- **similarity**. This keeps the exact similarity these two nodes have with each other, according to the outlier detection application.
- **threshold**. This keeps the exact threshold the user chose when he started the application. It is used along with the actual similarity the nodes have with each other by the client to draw the edge with the appropriate color. An edge has a green color if the two connecting motes are similar or red if they are not.

Since this entity is being changed periodically, these data are stored on the memory. When the user decides to stop the execution of the query, the stored data are transferred to the outlierEdgesFinal table which includes the id of the current session as a foreign key for future reference.

6.2.6 Occupied

The sensor network can only be operated by a single user. Therefore a mechanism had to be implemented to avoid the access of multiple users on the same network. The "Occupied" table is used as a part of this mechanism. When a user chooses to execute a query on the network the occ value turns from false to true.

Now, if a new user chooses to run a new query while the system is busy, a message shows up, informing the user that this action is not allowed. Since responsible for the interconnection between the server and the client is actually the python script, as we mentioned on the previous chapter, there is an expected latency between the time in which the user presses the stop button and the actual execution of the stopping query on the sensor network. So this table changes back to false only when this procedure has been completed and the sensor network has been reinitialized and is therefore ready to accept new connection.

6.3 Relational Schema

The EER schema of the database is translated into a Relational Schema that reflects the tables used in the database. Table 6.1 shows exactly how each of these entities are transformed into relations.

Table name	Attributes
Users	Username, Password, Name, Lastname, Avatar, AccountCreatedOn, LastLoggedIn, Mail
Edges	id, parentNode, childNode, depth, sessionIDfk (FK)
Measurements	id, measurements, isTemperature, measurementReceivedOn, sessionFKey (FK)
OutlierEdges	id, nodeOne, nodeTwo, createdOn, hasChanged, similarity, threshold
OutlierEdgesFinal	id, nodeOne, nodeTwo, createdOn, hasChanged, similarity, threshold , sessionIDfk (FK)
Session	sid, UserFK (FK), hasFinished, startedAt, finishedAt, isitoutlier, queryOrFunc, thresholdOrTct, period
Occupied	occ

TABLE 6.1: *Relational Schema.*

Attributes that function as primary keys are underlined, while attributes that function as foreign keys clearly declare it by having the (FK) next to their name.

6.4 Summary

In this chapter we described the database design implemented for this application. This design operates as the backbone of our system. Since the web service is stateless, database tables are used to represent some sort of state when this is required. To sum up, in this section we described the analysis of the database design, by analyzing the enhanced entity relationship model (EER) and the relational schema used for the synthesis of the database tables.

Chapter 7

Android Application

7.1 Introduction

In this chapter, we describe the implementation of the Android application. This app is what the end user utilizes to interact with our system. This application should provide easy-to-use functionality, as the end-user could be virtually anyone. Additionally, a certain level of abstraction had to be implemented, because users without any prior knowledge of sensor networks, databases or web services should be able to operate our system without any problems.

7.2 Mobile Limitations

Since the targeted medium in our occasion is a mobile device, we should take into account several limitations that are bound together with these devices. Firstly, their processing power is significantly lower when compared to conventional computers. Therefore, it is preferable to execute complex calculations on the server side, and just let the client consume these results.

Additionally, battery consumption is undoubtedly a major factor. Poorly written applications, often use resources that are not really necessary, thus resulting in higher power consumption. A higher battery consumption results in a lower battery life and in a disappointed user that will uninstall our application in no time.

Storage is another important issue on these devices. Especially older devices, have very limited space that can be used by third-party applications. Since we wanted to allow the vast majority of the Android users to be able to run our application, we had to make sure that the size of our executable file was kept to the minimum.

The data transmission takes place over a WiFi or a mobile network (3G - 4G). In this case the actual mobility of such devices works against us. The device can easily be disconnected from the network, and if this is not bad enough, the bandwidth can be very limited. It is therefore essential, to keep the transmitted messages small and to limit unnecessary data transmission. Caching is a method that can be used to limit these data transmissions and was extensively used in this application. With caching certain data that have been transmitted in the past are stored locally on the device. As a result, if they are needed again they can be accessed directly from the cache, thus avoiding an unnecessary connection with the web service.

Furthermore, since our target devices are mobile phones with limited screen size it is significant to take into account that limited screen real estate. Moreover, another relative issue is the fact that there are many Android powered devices with very different screen sizes. As a result, it is really important to make sure that our application will have the same "feel" when running on completely different screen sizes.

7.3 Abstraction

Certain elements/actions can require a specific knowledge of the terminology in order to be used correctly. However it is essential to be able to hide any unnecessary elements/actions that can confuse the user. Additionally, while it is important for the user to be informed about the current state of the application at all times, a certain level of abstraction had to be implemented in order to avoid the display of unnecessary data that may confuse him or her.

In order to achieve this, many operations are performed on the background, thus creating a more natural flow of the UI. When useful information are received, the operations that run on the background gain access of the UI thread and perform changes on the screen layout. Additionally, pop up messages inform the user about certain changes that occur on the background. That way the user is always aware about what happens, not only on the client side, but on the server side and the sensor network as well.

7.4 Blocking - Non blocking Operations

There are two kinds of actions that involve the execution of code on the background, blocking and non blocking. The first one requires the completion of a specific piece of code, before continuing to any further actions. For example, when the user tries to log in, a special method is called on the background that is responsible for sending the

username and password to the server in order to identify him. After these data have been transmitted, the client awaits for the response from the server to continue.

The reason why this operation is performed on the background is because a loading screen has to pop up in the foreground. If these operations take place on the foreground, the application will freeze. Obviously, if something like this happens the user will be confused. There is no possible way of knowing if the application is not responding because it crashed, or because the execution of a specific block of code is taking place. On the other hand, a loading screen prohibits the user from taking any more actions (except from canceling the identification) while at the same time it clearly informs him that an operation takes place, so he should wait. If the identification is successful the loading screen fades and a screen with the main menu loads up, to enable him take further actions.

When the measurement retrieval application is executed, again a certain piece of code runs on the background periodically checking if a new measurement has been retrieved. The difference is that now the user can perform actions, such us selecting to view the nodes of the created tree, select to view the graph with the measurements, zoom into the graph, choose to see a list with the individual measurements, and so forth. In this occasion, there is no loading screen prohibiting the user from performing the above-mentioned actions, because it is unnecessary.

The obvious difference between these two occasions is that in the first one a certain action has to be performed before continuing to the next, while the same does not apply to the second one. Specifically, on the first occasion we need to be certain that the user has logged in before showing him the main menu screen. If the user has not created an account, a message is being displayed informing him about this fact and suggesting to create one. However, on the second occasion, the fact that we periodically check for new measurements does not change the sequence of the execution. This of course changes drastically in case the user selects to stop the query. In that case, a stopping query is sent to the service and is being forwarded through the sensor network, while the periodically executed functions that request newer measurements cease their execution.

7.4.1 Android's AsyncTask

Thankfully Android OS provides a useful Class that enables the execution of background operations without having to manipulate threads and handlers. Thread is a concurrent unit of execution. Each thread has its own call stack for methods being invoked, their arguments and local variables. Each Java virtual machine has at least one main thread running, which started when the VM was launched, but an application can launch

additional threads while running. Threads in a single VM can interact with each other by using shared libraries and monitors associated with these objects.

While AsyncTask is a very useful tool that makes the execution of background operations a specifically easy task, it does not constitute a generic threading framework. It should be used for short operations with a small duration of a couple of seconds at most. An asynchronous task is defined by 3 generic types, called Params, Progress and Result, and 4 steps, called onPreExecute, doInBackground, onProgressUpdate and onPostExecute.

AsyncTask must be an inner class to be used and it should override at least the doInBackground method. The three generic types are the following:

1. **Params**, the type of the parameters sent to the task upon execution.
2. **Progress**, the type of the progress units published during the background computation.
3. **Result**, the type of the result of the background computation.

The 4 steps the asynchronous task follows are the following:

1. **onPreExecute()**, invoked on the UI thread before the task is executed. This step is normally used to setup the task, for instance by showing a progress bar or a loading screen on the user interface.
2. **doInBackground(Params...)**, invoked on the background thread immediately after onPreExecute() finishes executing. This step is used to perform background computation that can take a long time. The parameters of the asynchronous task are passed to this step. The result of the computation must be returned by this step and will be passed back to the last step. This step can also use publishProgress(Progress...) to publish one or more units of progress. These values are published on the UI thread, in the onProgressUpdate(Progress...) step.
3. **onProgressUpdate(Progress...)**, invoked on the UI thread after a call to publishProgress (Progress...). The timing of the execution is undefined. This method is used to display any form of progress in the user interface while the background computation is still executing. For instance, it can be used to animate a progress bar or show logs of the completed percentage in a text field.
4. **onPostExecute(Result)**, invoked on the UI thread after the background computation finishes. The result of the background computation is passed to this step as a parameter. If a progress bar or a loading screen has been used this is a great point to dismiss it.

7.4.2 Android's Background Service

Let's say that an Android application requests some measurements from the server but the returning values have to be displayed on more than one screens. Since the data that are about to be displayed are the same, it is rather inefficient to use AsyncTasks on each of those screens to request them multiple times. On the other hand, we could request the data using a single background operation and store them locally on the phone. That way when these data are needed again they can be accessed directly from the phone.

Since, AsyncTask will be used to access the data from the internal memory of the phone, we had to find a way to periodically check for new measurements on the sensor network. Android API provides a useful component called Service. Services are components that operate on the background and perform long-running operations. They do not provide a user interface and the biggest advantage is that it can be fired from an activity class used to display a screen, and continue running on the background even if a new screen or even a new application has loaded.

Additionally, a component can bind to a service to interact with it or even perform interprocess communication (IPC). A service can essentially take two forms:

1. **Started** When a service is started by another component such as an activity, it can run on the background indefinitely, even if the component that started it gets destroyed. Usually, when a service is just started and not bound, it is used to perform a single operation that takes a lot of time and it is not expected to return anything to the caller.

   A great example that shows the power of this component, is the uploading of a file to a server. This action may require a lot of time to perform so it cannot be executed from the UI thread as it will freeze until the uploading is finished. Additionally, it does not have to return anything to the calling activity, when the file is uploaded the service can terminate itself. If we want to find out whether the action was completed, the activity can check if the service is terminated or still running by using a function provided by this API.

2. **Bound** A service is bound when the function bindService() is called by an application. A bound service offers a client-server interface within the same device that allows components to interact with the service, send requests, get results, and even perform these interaction across processes using interprocess communication (IPC). A bound service runs only as long as another application component is bound to it. Multiple components can bind to the service at once, but when all of them unbind, the service is destroyed.

Although the documentation on Android Developers generally discusses these two types of services separately, a service can work both ways. It can be started (to run indefinitely) and also allow binding. It is simply a matter of whether callback methods are implemented. The methods that have to be implemented are: onStartCommand(), to allow components to start it and onBind(), to allow binding.

Regardless of whether a service is started, bound, or both, any application component can use the service (even from another application), in the same way that any component can use an activity by starting it with an Intent. However, services can be declared as private in the manifest file, and block access from other applications.

A service runs in the main thread of its hosting process. The service does not create its own thread and does not run in a separate process (unless it is specifically declared otherwise). This means that, if a service is going to do any CPU intensive work or blocking operations (such as MP3 playback or networking), a new thread should be created within the service to do that task. By using a separate thread, the risk of Application Not Responding (ANR) errors will be reduced and the application's main thread can remain dedicated to user interaction with other activities.

7.5 Storage Option

In this application, a service was used, as we mentioned previously, to request new measurements from the server and the various activities were used to display them in more than one screens. In order to store these measurements locally, we had to choose between the storage options provided by Android OS.

The storage options are the following:

- **Shared Preferences**, store private primitive data in key-value pairs.
- **Internal Storage**, store private data on the device memory.
- **External Storage**, store public data on the shared external storage.
- **SQLite Databases**, store structured data in a private database.

7.5.1 Shared Preferences

This is a general framework that allows developers to save and retrieve persistent key-value pairs of primitive data types. Primitive data types that can be stored include:

booleans, floats, ints, longs, and strings. This data will persist across user sessions (even if the application that stored it, is killed).

7.5.2 Internal Storage

Files can be stored directly on the device's internal storage. By default, files saved to the internal storage are private to the application that stored them and other applications cannot access them (nor can the user). When the user uninstalls the application, these files are also removed.

If the programmer wants to temporarily cache some data, rather than store them persistently, he could use a provided method of the internal storage that enables him to save temporary cache files. When the device is low on internal storage space the OS may delete these files to recover space. Again, in this occasion when the user decides to uninstall the applications these files are also removed.

7.5.3 External Storage

Every Android device supports a shared external storage that can be used for data storage. In some devices this storage refers to an inserted SD card while in others it refers to an internal storage unit(such as a hard drive in the device). These files are reachable from anyone. The user can access them if he connects the phone via a USB cable to a computer while other applications can access them if they are aware of the filenames. In case a device includes an internal memory along with an SD card slot, this method uses only the internal memory unit to store the files.

7.5.4 SQLite Databases

Android provides full support for SQLite databases. Any created databases will be accessible by name to any class in the application, but not outside of the application. SQLite is a relational database management system with a very small overhead. In contrast to other database management systems, SQLite is not a separate process that is accessed from the client application, but an integral part of it.

The SQLite library is linked in the application program. The application uses SQLite's functionality through simple function calls, which reduce latency in database access, since function calls within a single process are more efficient than inter-process communication. SQLite read operations can be multitasked, though writes can only be performed sequentially.

Since this was the most advanced, fast, and easy-to-use storage option, without any security risks we decided to use it. When the user tries to log in, execute an aggregation query or perform any action that may require the exchange of valuable data, SQLite was used to store these data locally in case the are needed in the future. That way, they can be accessed faster and without adding an additional burden on the network.

Additionally, a very powerful tool included in the Android SDK, is sqlite3. This tool allows the developers to browse table contents, run SQL commands, and perform other useful functions on SQLite databases. ADB command shell can be used to initialize the sqlite3 command-line program and manage the SQLite databases created by any Android applications. The sqlite3 tool includes many useful commands, such as .dump to print out the contents of a table and .schema to print the SQL CREATE statement for an existing table. The tool also allows developers to execute SQLite commands on the fly.

7.6 kSOAP2

As we mentioned earlier we used a SOAP web service to feed the client with the needed information. Unfortunately, Android OS does not natively support the interaction with SOAP web services. Additionally, while JAX-WS framework (which was used for the development of the web service) could also be used to generate the client stubs, which would enable the client-server communication, the overall size of the application would have been extremely big for a mobile application.

Stubs are seemingly simple methods that work in the same way conventional methods (functions) work. What makes stubs so interesting is the fact that when these functions are called, instead of locally executing a piece of software, a call is initialized to a remote server. This server uses the transmitted-over-the-network arguments, and responds with another message. Sadly though, the generating stub methods created by JAX-WS framework are usually used by java applications intended to run on conventional computers. As a result, the main restriction in using the auto-generated JAX-WS stub methods is the fact that the generated API, is usually too big. As mentioned, it is rather significant to be able to keep the overall size of our Android application to the minimum. So, if our application has an average size of 1-2 MB and the generated API alone is more than 15-25 MB, it is rather inefficient to use this API for our client-server communication.

After a long search we were able to find an API that seemed to be perfect for our case. kSOAP2-android provides a lightweight and efficient SOAP client library for the

Android platform. It is a fork of the kSOAP2 library that is tested mostly on the Android platform, but should also work on other platforms that use Java libraries. kSOAP2 is also still using Java 1.3, so it should work fine on JavaME, Blackberry and so on. Furthermore, ksoap2-android is licensed under MIT and can therefore be included in any commercial application.

Bellow is a slice of code that shows exactly how kSOAP2 can be used to connect to a web service:

```
1  public class LoginActivity extends Activity {
2  // declaration of Web Service's namespace,
3  // method and SOAP action
4   private static final String NAMESPACE =
5      "http://tiny_service/";
6   private static String URL;
7   private static final String METHOD_NAME =
8      "requestUser";
9   private static final String SOAP_ACTION =
10     "http://tiny_service/SensorWebService";
11     // This gets executed when a new screen
12     // loads up in Android.
13  @Override
14   public void onCreate(Bundle savedInstanceState) {
15    // get the URL of the WSDL file of the
16    // web service from Android resources
17    // if we choose to host the service
18    // on a new URL just change the specific
19    // resource instead of changing every
20    // URL from every activity.
21    URL = this.getString(R.string.StringWithURL);
22    //...
23    //more code
24    //call asynchronous task
25    //...
26    // This is AsyncTask. We talked about it before
27    // This method is executed on the background
28    @Override
29    protected String[] doInBackground(Void... voids) {
30    // use kSOAP's objects!
```

```
31      SoapObject request = new SoapObject(NAMESPACE,
32          METHOD_NAME);
33      PropertyInfo propInfo=new PropertyInfo();
34      propInfo.name="User";
35      propInfo.type=PropertyInfo.STRING_CLASS;
36
37      // ... more code ...
38
39      request.addProperty(propInfo,
40       serializeLoginForm(username.getText().toString(),
41       password.getText().toString(), retFromtDB));
42       SoapSerializationEnvelope envelope = new
43        SoapSerializationEnvelope(SoapEnvelope.VER11);
44       envelope.setOutputSoapObject(request);
45       HttpTransportSE androidHttpTransport =
46       new HttpTransportSE(URL);
47       // Try calling the Web Service!
48       try {
49        androidHttpTransport.call(SOAP_ACTION, envelope);
50        // get the response message!
51        SoapPrimitive  resultsRequestSOAP =
52        (SoapPrimitive) envelope.getResponse();
53        // ... more code ...
54        // check for errors then
55        // parse it and then display it on the
56        // foreground if everything was OK!
57
58
59
60  }
```

Listing 7.1: kSOAP2-android implementation example

Notice that the developer has to specifically declare the name of the calling function, the namespace and the SOAP action of the web service, along with the URL were the WSDL file can be found. Usually none of these are necessary when auto-generated stubs are used instead.

While this is much more error prone, the fact that kSOAP adds only a couple of hundreds kB when included in a project, makes it perfect for mobile applications. The

executable file of mobile applications is important to stay as small as possible due to the aforementioned limited space of mobile phones.

7.7 User Interface

In every application perhaps the most important part, apart from the actual functionality, is the user interface. This is the part that the end user interacts with, so a well designed user interface is crucial. Human - computer Interaction (HCI) is a particularly interesting field, that involves the study, planning, and design of the interaction between people (users) and computers.

Attention to human-machine interaction is important because poorly designed human-machine interfaces can lead to many unexpected problems. A famous example is the "Three Mile Island accident". This was a partial nuclear meltdown that occurred in USA and it is believed that this problem arose because of a poorly designed interface. In particular, a hidden indicator light led to an operator manually overriding the automatic emergency cooling system of the reactor. The operator mistakenly believed that there was too much coolant water present in the reactor and enabled the steam pressure release but instead a nuclear meltdown was caused.

A long term goal of HCI is to design systems that minimize the barrier between the human's cognitive model of what they want to accomplish and the computer's understanding of the user's task. A set of rules about the do-s and don't-s has been developed over time. Since this is a mobile application, this part is even more challenging, when compared to a desktop or a web application. The fact that user input is not based on the use of a hardware keyboard and mouse but on the screen touch, requires the designing of buttons and other UI elements that are big enough to be "pressed" by a finger but on the other hand, the limited screen real estate of mobile phones limits the number of UI elements that a single screen can contain.

7.7.1 Android Layouts

A layout defines the visual structure for a user interface, such as the UI for an activity or app widget. A layout can be declared in two ways:

- **XML UI Elements** Android provides a straightforward XML vocabulary that corresponds to the View classes and subclasses, such as those for widgets and layouts. XML resembles the HTML and CSS code that every web page contains.

- **UI Elements Manipulated on Runtime** An application can create View and ViewGroup objects (and manipulate their properties) programmatically. This resembles the code that every dynamic web page contains.

The Android framework provides the option to use either or both of these methods for declaring and managing the application's UI. For example, the default layout elements can be declared in XML along with the screen elements that will appear in them and their properties. Additionally, the code that is being executed on run-time can add or modify the state of those elements, thus generating a more dynamic feel of the UI.

The fact that Android enables the developer to declare the UI in XML, helps in separating the presentation of the application from the code that controls the behavior. The UI description is not inextricably linked to the application code. This means that modifications can occur without requiring any adjustments on the source code. Additionally, declaring the layout in XML makes it easier to visualize the structure of your UI, so it is easier to debug problems.

In general, the XML vocabulary for declaring UI elements closely follows the structure and naming of the classes and methods, where element names correspond to class names and attribute names correspond to methods. In fact, the correspondence is often so direct that the link between the XML attribute and the corresponding class method (and vise versa) can be easily guessed. However, not all vocabulary is identical. In some cases, there are slight naming differences. For example, the EditText element has a text attribute that corresponds to EditText.setText().

The following XML code is used to create a simple log-in form:

```
1  <?xml version="1.0" encoding="utf-8"?>
2  <RelativeLayout
3    xmlns:android="http://schemas.android.com/apk/res/android"
4    android:layout_width="fill_parent"
5    android:layout_height="fill_parent"
6    android:fillViewport="true"
7    android:background="#680000"
8    >
9     <!-- Action Bar -->
10    <RelativeLayout
11    android:id="@+id/actionbar"
12    android:layout_width="fill_parent"
13    android:layout_height="50dp"
```

```
14    android:layout_alignParentTop="true"
15    android:background="#181818">
16        <!-- Name of the application -->
17        <TextView android:text="Androiny"
18        android:textSize="20dp"
19        android:layout_centerInParent="true"
20        android:layout_width="wrap_content"
21        android:layout_height="wrap_content"/>
22    </RelativeLayout>
23      <!-- Make it scrollable -->
24      <ScrollView xmlns:android=
25      "http://schemas.android.com/apk/res/android"
26      android:id="@+id/ScrollView01"
27      android:layout_width="wrap_content"
28      android:layout_height="wrap_content"
29      android:layout_below="@id/actionbar"
30      android:background="#680000">
31          <RelativeLayout
32             android:layout_width="fill_parent"
33             android:layout_height="wrap_content"
34             android:background="#680000"
35          >
36           <!--  Header  Starts-->
37             <LinearLayout android:id=
38             "@+id/header"
39             android:layout_width="fill_parent"
40             android:layout_height="wrap_content"
41             android:paddingTop="5dip"
42             android:paddingBottom="5dip">
43
44             </LinearLayout>
45             <!--  Header Ends -->
46             <!-- Area Before Form Start -->
47             <LinearLayout android:id="@+id/footer"
48               android:layout_width="fill_parent"
49               android:layout_height="90dip"
50               android:background="#680000"
51               android:layout_alignParentBottom="true">
52             </LinearLayout>
```

```
53              <!-- Area Before Form Ends -->
54              <!-- Login Form -->
55              <LinearLayout
56               xmlns:android="http://schemas.android.com/
57                    apk/res/android"
58               android:orientation="vertical"
59               android:layout_width="match_parent"
60               android:layout_height="wrap_content"
61               android:background="#680000"
62               android:padding="10dip"
63               android:layout_below="@id/header">
64               <!--  Username Label -->
65               <TextView android:layout_width="fill_parent"
66                android:layout_height="wrap_content"
67                android:textColor="#ffffff"
68                android:text="Username"/>
69               <EditText android:layout_width="fill_parent"
70                android:id="@+id/username"
71                android:layout_height="wrap_content"
72                android:layout_marginTop="5dip"
73                android:layout_marginBottom="20dip"
74                android:singleLine="true"/>
75                <!--  Password Label -->
76                <TextView android:layout_width="fill_parent"
77                 android:layout_height="wrap_content"
78                 android:textColor="#ffffff"
79                 android:text="Password"/>
80                <EditText android:layout_width="fill_parent"
81                 android:id="@+id/password"
82                 android:layout_height="wrap_content"
83                 android:layout_marginTop="5dip"
84                 android:singleLine="true"
85                 android:password="true"/>
86                <!-- Login button -->
87                <Button android:id="@+id/btnLogin"
88                 android:layout_width="fill_parent"
89                 android:layout_height="wrap_content"
90                 android:layout_marginTop="10dip"
91                 android:text="Login"/>
```

```
92              <TextView android:id="@+id/signup"
93               android:layout_width="fill_parent"
94               android:layout_height="wrap_content"
95               android:layout_marginTop="20dip"
96               android:layout_marginBottom="40dip"
97               android:text="New to Androiny? Signup here"
98               android:gravity="center"
99               android:textSize="15dip"
100              android:textColor="#ffffff"/>
101           </LinearLayout>
102          <!-- Login Form Ends -->
103    </RelativeLayout>
104  </ScrollView>
105
106 </RelativeLayout>
```

Listing 7.2: XML responsible for the creation of the log in screen.

This displays the screen showed on figure 7.1

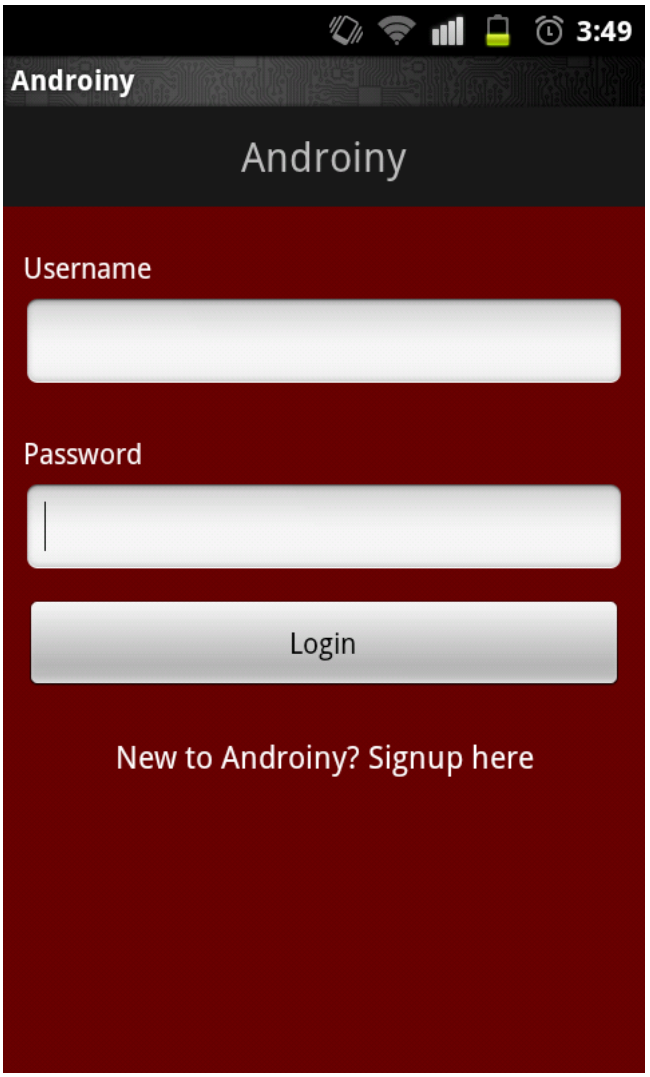

FIGURE 7.1: *Login Screen.*

7.7.2 Action Bar

Android's action bar is a window feature that identifies the application and user location while it also provides actions and navigation modes. This component can be used to present user actions or global navigation.

Action bars offer consistency on the user interface across the various screens, within an application. Additionally, since Android devices come in very different screen sizes, the fact that this feature gracefully adapts into each of those screen sizes, is a very significant feature. Moreover, since this element is extensively used by many applications, including applications developed by well-known companies, such as Facebook, Google, Twitter and so forth, the user does not have to spend time familiarizing himself to this feature.

This component can be used when specific UI elements need to be easily accessible by the user. It can be used to host elements such as share buttons, that enable the users to share content on famous social network websites, navigation buttons such as back, home or menu buttons. These buttons seem to be ideally placed inside the action bar, as they have to be particularly easy to spot. Undoubtedly, the application's name or the name of the specific screen or even loading screen icons can be added on this component to help the user understand the current state in which the application is in.

The only drawback of this component is the fact that it is intended to run on Android 3.0 (API level 11) and above. While Android provides the option to use this component on older Android versions, there is a limitation on the functionality that can be supported by them. Since, as we mentioned earlier this application was created while keeping in mind the fact that it is important to be compatible not just with recent high-end devices but, with older and more low-end devices as well, it seemed appropriate to create our own Action bar widget to support the functionality we anticipated, and at the same time avoid these limitations.

At figures 7.6 various Action Bars are displayed. It is easily noticeable that on the center of the action bar, the name of the application is positioned. On the left there is positioned a button that has always exactly the same functionality the hard-key back button has, which is stopping the execution of the query or going back to the previous screen or the Main Menu screen. On the right, a button with an extra functionality is displayed. At times, this button is a log off icon placed there to inform the user that the application's state allows the logging of from our system. While on occasions when log off operations simply cannot be performed (for instance when a transaction with the web service, or a background operation is taking place) a loading screen icon is displayed instead.

7.7.3 Canvas

As we have mentioned multiple times, the main purpose of this application is to help the user operate a sensor network. Two operations are supported. The first one is to detect outlier nodes within the sensor network and the second one is to execute an aggregation query and inform the user about the measurements received from the sensor network. In both these occasions, the user has to be aware of the formed network. During the outlier detection functionality, the user has to be able to get information such as the outlier nodes and precisely view how different these nodes are from the neighboring ones. On the sensor measurement functionality, information about the created tree by the sensor network, has to be displayed.

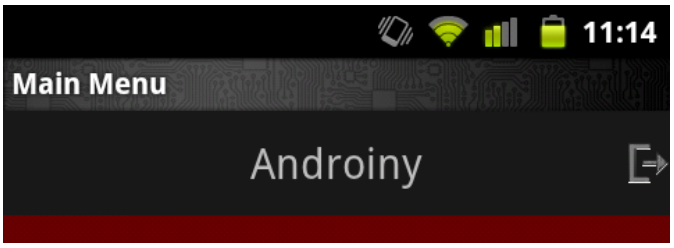

FIGURE 7.2: Action Bar on Main Menu Screen

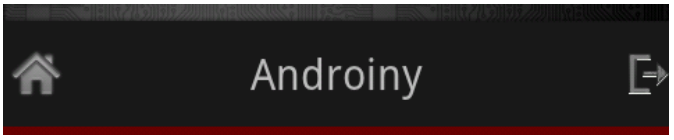

FIGURE 7.3: Action Bar on a Preview Screen

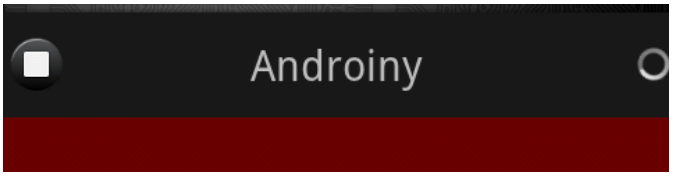

FIGURE 7.4: Action Bar while background operations are performed

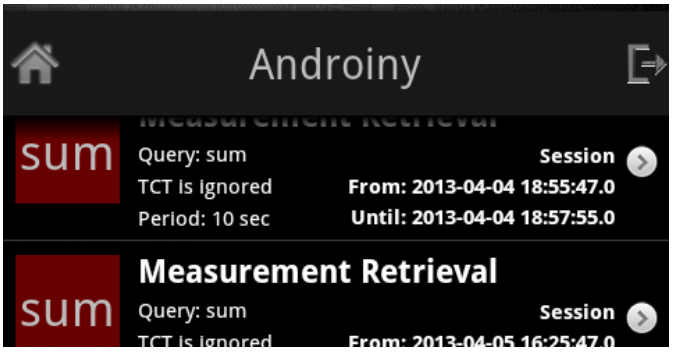

FIGURE 7.5: Action Bar on Screen Displaying preview Sessions

FIGURE 7.6: Action Bar Widgets

Instead of just informing the user about the created tree via simple messages, we wanted to create something far more lifelike. The motes had to be visualized as nodes inside a tree, while edges should connect the interconnecting motes. It would also be a nice feature, if the user could manipulate this graph on the screen. He should be able to pan, zoom in and out and change the position of each node on the screen. That way the user experience would be much more lifelike for the user. Additionally, if a good looking interface with intense colors is developed alongside with this supported functionality, the result would be a very positive user experience alongside with a very satisfied user that will be happy to use our application again.

However the actual drawing of the graph was rather challenging. While a lot of visualization APIs are famous for their limitless visual effects, none of these had been successfully

ported for native Android applications by the time this projected started. Also, the existing Android API did not provide any tools that could be used for the visualization of the sensor network graph, and no third party API was able to visualize the sensor network exactly the way we wanted. Obviously, gaming engines used to develop video games for Android devices were excluded right away due to the fact that, while they do enable the developer to create very detailed graphics, the overall size of the application would be too big for our needs. After all, we should be able to run this application not only on high powered phones but on middle and low-ranged devices as well. Last but not least, several javascript libraries could be used, but that would create an additional load to the very limited bandwidth of the mobile devices. Additionally, many of those could not be rendered correctly on older devices.

Sadly, we had to create the graphics on our own again. Android API provides a framework API that enables the drawing of 2D shapes. That way custom low-level graphics could be rendered into a canvas. It should be mentioned that this part was extremely hard to implement, because we could not use a middle layer that would be responsible for the creation of the graphics and the animations using simple calls. Everything should be performed manually. We had to draw simple circles (used to represent the motes) on a canvas and display it on the fly while at the same time animations had to be implemented to provide feedback on the users' actions.

Every time the user decided to execute a query on the sensor network, and the sensor network responded via the web service with all the necessary information about the specifics of the formed tree or graph, an actual representation of this tree or graph had to be displayed on the screen. This means that during this transaction the Android application had to create the shapes that represented the motes, and each of those had to be positioned using specific coordinates into the canvas. The radius of the nodes and the exact coordinates had to be specifically selected in a way that would not let the nodes appear outside of the visible canvas, while at the same time, if a tree was shown the user had to be able to see from the visualization the exact depth it had on that tree. Additionally, special care should be given in order to avoid two or more nodes appearing on top of each other. The fact that this application is supposed to run on Android devices with very different screen sizes, and the fact that the number of nodes can change drastically from the first execution to the next, made the drawing of this graph particularly challenging.

Furthermore, an actual animation had to be performed. When the user chooses to pan the screen a sensor actually tracks the movement of his finger and computes exactly how fast or slow and in which direction the finger is "traveling" in order to animate the movement of these nodes to the same direction. In order to do this efficiently,

some sort of sampling was implemented. Instead of endlessly monitoring the movement and changing the coordinates of each of these nodes and edges, which would have been extremely power consuming, a simple timer was used that gets fired periodically every a couple of hundred milliseconds and computes the difference between the last X-Y coordinates of the finger and the newest ones. Of course the coordinates of the drawn elements are changed accordingly, thus creating the illusion of animation.

Something similar was implemented to enable the zoom-in and zoom-out effect. A very famous gesture that is extensively used on multi-touch screens, is the pinch-to-zoom gesture. During this gesture, the user uses two fingers to zoom in or out of the displaying graphics. In order to zoom in, the user's two fingers draw away from each other and the exact opposite is performed to zoom out. This gives a feeling of direct manipulation on virtual objects. This gesture along with the panning gesture, gives the illusion of manipulating digital shapes as if they were real-life objects placed upon a surface. Since Android 1.6 multi-touch gestures are allowed, so we added this feature to make the user experience better. However, we had to use the canvas to visualize this action, so we had to manually count the distance that the two fingers "traveled" and use this number to manually change the sizes of the lines and the radius of the circles.

Figures 7.7 and 7.8 show some of the drawings on the canvas.

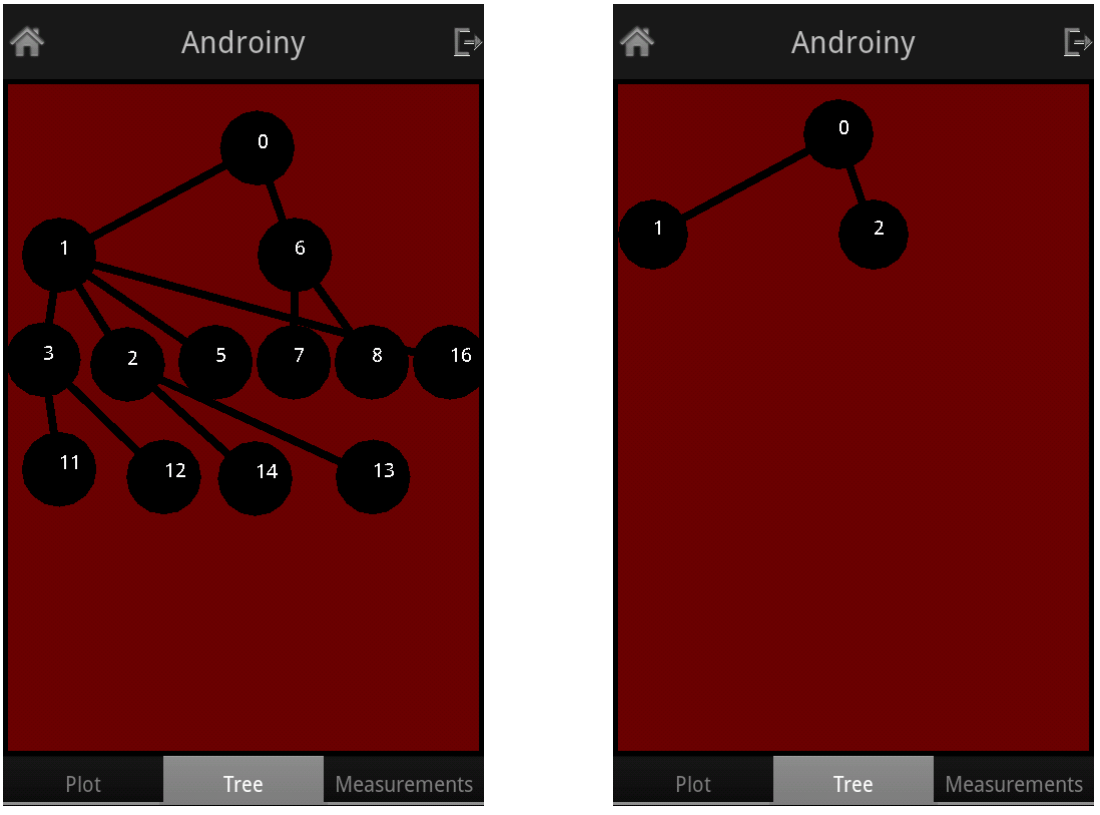

FIGURE 7.7: Canvas Drawings for Sensor Measurements

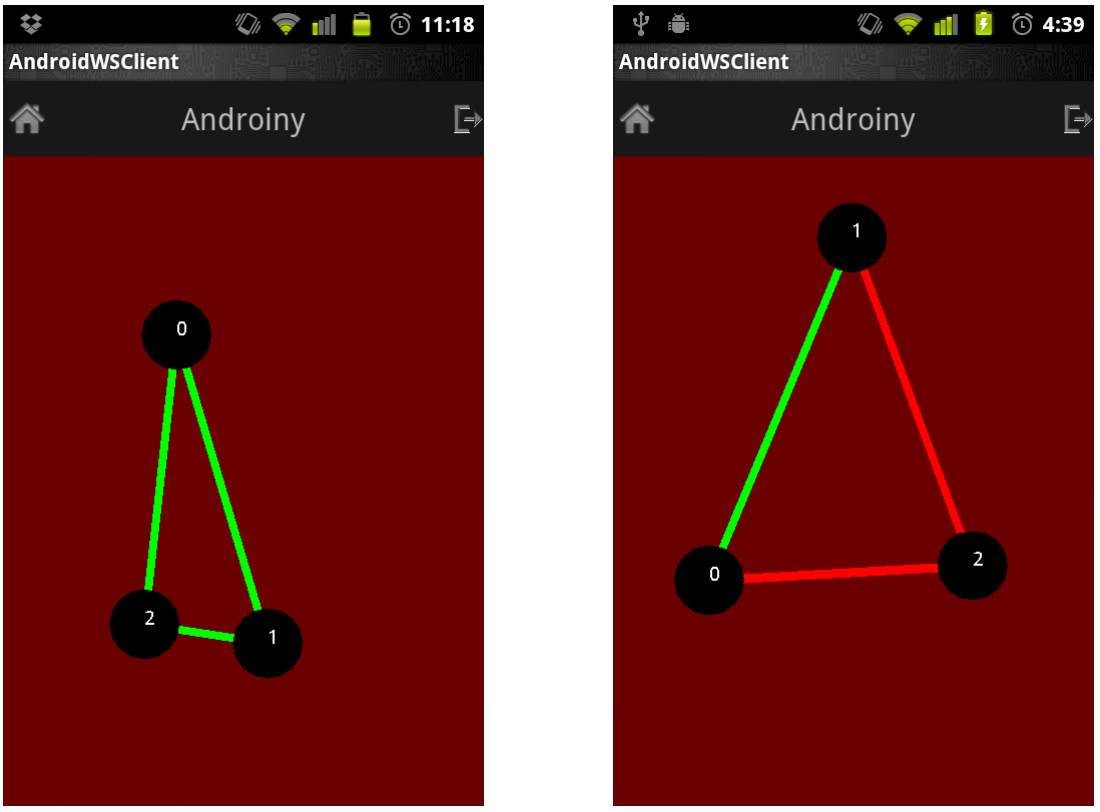

FIGURE 7.8: Canvas Drawings for Outlier Detection

7.7.4 AChartEngine - A Charting Library for Android Applications

AChartEngine is a charting library available for use in Android Applications. It supports all the Android SDK versions starting from 1.6. Since as we mentioned versions prior to Android 1.6 do not support pinch to zoom gestures, it displays zoom in and out buttons to cover this functionality. By the time these words were written the devices that used a version of Android from 1.6 and above were more than 99% in a global scale.

Adding charting to an Android application with AChartEngine, is as simple as adding the achartengine-x.y.z.jar to the application classpath and start coding against its APIs. The jar file is only 110 KB in size, which is quite a small footprint for an Android application. However, AChartEngine offers support for many chart types.

AChartEngine currently supports the following chart types:

- Line Chart
- Area Chart
- Scatter Chart
- Time Chart

- Bar Chart
- Pie Chart
- Bubble Chart
- Doughnut Chart
- Range (high-low) Bar Chart
- Dial Chart / Gauge
- Combined (any combination of Line, Cubic Line, Scatter, Bar, Range Bar, Bubble) Chart
- Cubic Line Chart

All the above supported chart types can contain multiple series, can be displayed with the X axis horizontally or vertically and support many other custom features. The model and the graphing code is well optimized such as it can handle and display huge number of values.

In figures 7.9 and 7.10 some examples can be viewed that show the potential of this charting library.

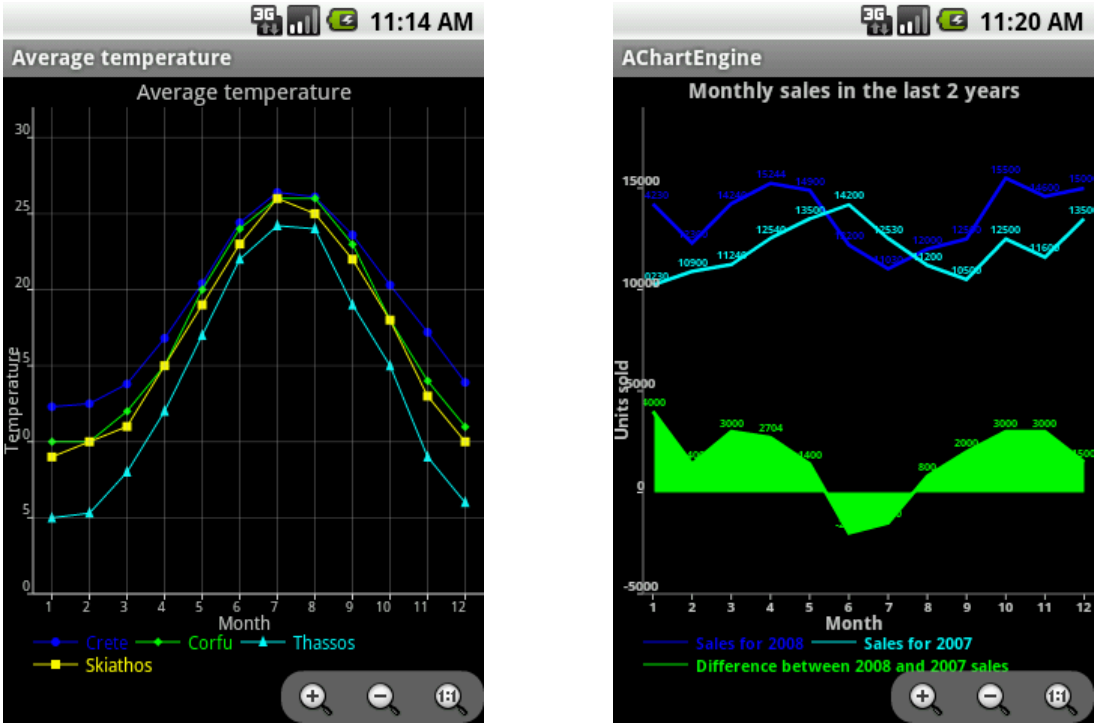

FIGURE 7.9: AChartEngine examples for mobile phone

FIGURE 7.10: *AChartEngine examples for tablet.*

Figures 7.11, 7.12, 7.13 show how the sensor measurements are being displayed. Since we wanted to have as much space as possible for these screens, we chose to display these images on full-screen. This means that the notification bar which usually appears on top of the screen is now hidden. Since the user wants to be able to view these graphs with as many details as possible, and since this application can be executed even on devices with screens sizes less than 3 inches, it appeared to be a good idea to display these activities on full screen. After all, it is important to draw the attention of the user to the measurements while executing a query. If the user ends the execution of a query and decides to return to the Main menu, the screen will restore its size allowing the notification bar to be viewed again.

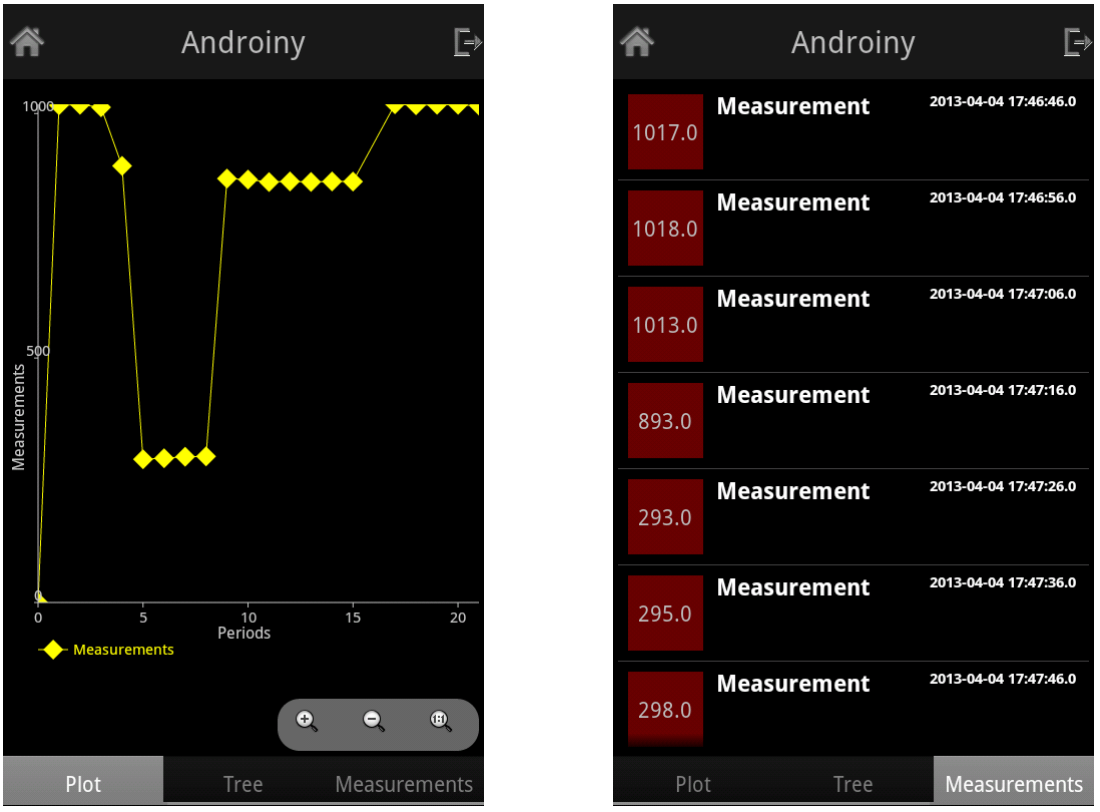

FIGURE 7.12: Execution of a Summary Query

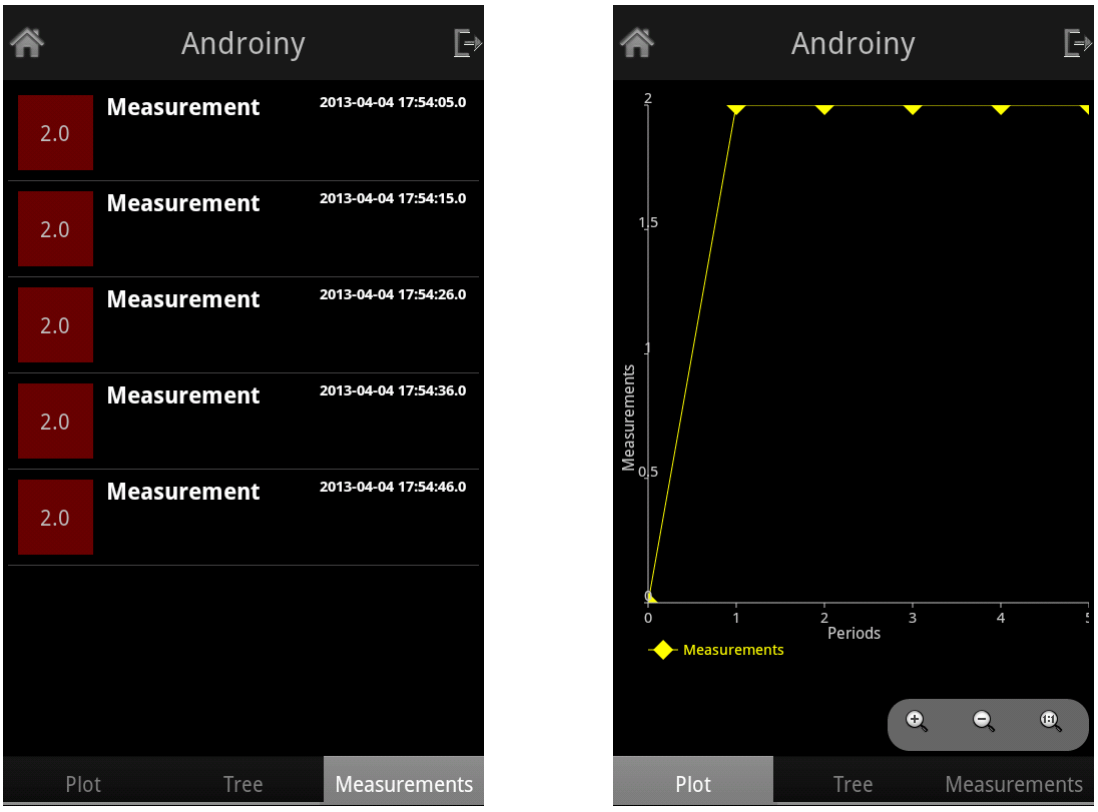

FIGURE 7.13: Execution of a Count Query

7.8 Summary

To sum up, the client application is perhaps the most important component of our system. While the code itself is not as challenging as the TinyOS application (even if the overall number of lines was extremely high when compared to the web service or the TinyOS application), there were many aspects that had to be taken into consideration. Firstly, the look and feel of the application had to be appealing. It is important to make the user feel satisfied after using our application, so we had to make sure that warm, and cheerful colors were used instead of cold or dark colors which are known to generate negative emotions. Apart from good-looking, the application had to be useful. Users are expected to operate a sensor network while on the go, so it is very important to have an easy-to-use interface. In order to achieve this, we used graphic elements that are already well-known to Android users as they have been used extensively on other famous Android applications.

Furthermore, it seemed to be particularly important to make the application fast and responsive. It is important to avoid latency and the same applies to freezes. This is especially true when the operator is in a hurry, or trying to multitask. Therefore, we had to make sure that the exchanging messages had to be limited in size and frequency.

When the requirements of the application would not let as avoid big messages, caching mechanisms were implemented. That way we made sure that the future messages would be far smaller in size. While in case the frequency, in which messages were transmitted could not be limited, we chose to perform many of these exchanges on the background and store the received data locally on the device, before they were actually needed. It is noteworthy that all of this takes place without bothering the user, or distracting him by showing annoying pop up loading screens.

Chapter 8

Conclusion

8.1 Summary

In this thesis implementation, we created a complete system that enables the manipulation of a sensor network using a mobile application. The user of this system is able to execute operations such as simple sensor measurement retrievals or outlier detection functionalities, without having to deal with bloated software that requires advanced programming skills to run. Additionally, while several applications have been developed in the past, enabling the direct manipulation of a sensor network, neither of them was free from certain limitations.

The vast majority of these applications is intended to run on older versions of the Windows operating system. Undoubtedly, there were some obvious restrictions that arose from this fact. The user had to specifically install outdated versions of an operating system he would not use for anything else. Dual/Triple-booting, installations of virtual machines and other complicated operations had to be performed in order for him to be able to operate a simple sensor network. Apart from that, he was forced to sit behind a screen in order to operate on the sensor network since Windows is a desktop operating system.

These limitations, certainly do not apply to our system. Firstly, the client program used by the end user to enable him interact with our system is an Android application. This application was developed while keeping in mind that it had to run flawlessly both on older and newer versions of Android. Additionally, since Android is a very popular operating system with millions of activations per day, it is rather self-explanatory that the target audience is particularly big in number, so there should not be any real limitations there. It is worth mentioning that, the fact that Android is such a successful

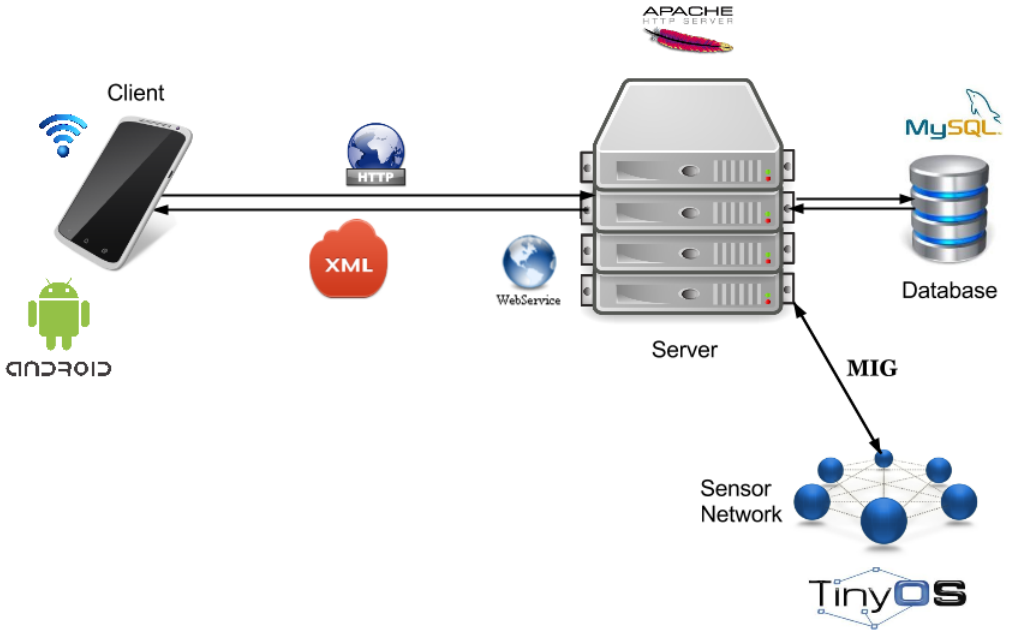

FIGURE 8.1: *Architecture of the Implemented System.*

operating system, works in our favor. A new cheap Android device can be purchased in a price lower than that of a sensor mote. This is far cheaper than buying a brand new computer, so there is also a certain advantage on this part too.

Perhaps the most important advantage of this system is the mobility factor. The users can be virtually anywhere and still be able to use our system, provided that there is an internet connection. The fact that this system is using a web service, as an intermediate level between the Android application and the actual sensor network can verify the flexibility that comes with our system. The web service also guarantees the security of our system, since the client cannot not operate directly on the sensor network. That way several activities performed by potential hackers with intentions to cause problems to our system, are limited. Additionally, since this is a SOAP application, there is literally no limitations concerning the operating system the server uses. The web service is hosted on conventional HTTP servers, such as Glassfish or Tomcat which run both on Windows and Linux operating systems.

8.2 Future Work

The work performed in the context of this thesis implementation can be used as the base for a several future implementations. some of which are listed below.

8.2.1 Web Application

While this system is natively supported by one of the most popular mobile operating systems, it is again subjected to limitations. In order for someone to use it, he has to own an Android device. However with minor work, a web interface of this system can be implemented in order for it to be supported by any device with internet access. The fact that the web service was implemented by an extensively used SOAP framework can act in our favor. An auto-generated API created by this framework can be used to link this potential web client with the web service and the sensor network.

The only thing the potential developer has to do in order to implement this web client is to just use this system and build upon it. By utilizing the functions and messages described in the WSDL file of this web service, he can actually interact with the sensor network. Obviously, in the same way, native clients intended to run on other operating systems can also be implemented. Since the messages are transmitted using SOAP and the actual useful information is in XML, it means that clients can use them regardless of the programming language used for their implementation.

8.2.2 Limit Bandwidth - Use Cache

While several actions have been performed in order to avoid the unnecessary transactions of the client with the web service, some additional work can also be performed. For the time being, SQLite databases have been used to store data such as avatar pictures, recently executed queries and so forth. A smart system can be implemented to perform these transactions before these actual data are requested. For example background operations could be used when the device is connected to a Wi-Fi network to make a complete copy of the data related to a specific user, that could be previewed when the device does not have internet access.

8.2.3 Additional Functionality for the Sensor Network

While two sensor network applications have been used by this system, additional functionality can be added in the future. Furthermore, expansion of the supported applications

can also be performed. For example a "group by" functionality can be added. With this functionality, the user will be able to place sensors on different environments (e.g. different rooms) and be able to view the the conditions in each of these environments separately.
