Abstract

Recently, technological advances have resulted in the wide availability of commercial products offering near-line, robot-based, tertiary storage libraries. Thus, such libraries have become a crucial component of modern large-scale storage servers, given the very large storage requirements of modern applications. Although the subject of optimal data placement (ODP) strategies has received considerable attention for other storage devices (such as magnetic and optical disks and disk arrays) the issue of optimal data placement in tertiary libraries has been neglected. The latter issue is more critical since tertiary storage remains three orders of magnitude slower than secondary storage. In this paper we address this issue by deriving such optimal placement algorithms. First, we study ODP in disk libraries (jukeboxes) and, subsequently, in tape libraries. In our studies we consider different scheduling algorithms, different configurations of disk libraries, and different tape library technologies (reflecting different existing commercial products) and show how these impact on the ODP strategy.

1 Introduction

In large scale storage servers which are configured to include multiple on-line and off-line storage media and which deal with a large number of requests with unpredictable access patterns, the problem of minimizing the cost of accessing data stored in all media is critical for the performance of the system.

[1]Authors address: MUSIC, P.O. Box 133, Chania Crete 73100 Greece. Email: {stavros, peter, fenia}@ced.tuc.gr. Support for this work was provided by the European Community through the ESPRIT Long Term Research Project HERMES no. 9141

In this paper we examine tape and disk libraries for which we derive data placement algorithms in order to optimize the access cost. Typical tape or disk libraries include a few drives and many more (typically a few hundreds) disks or tapes. Disks (tapes) are loaded onto the drives or unloaded from them by a robotic mechanism which typically consists of one arm. When a particular "loaded" object is requested the disk (tape) drive head first places the read head onto the disk (tape) location where the object resides and then reads the object. The components of the access cost which reflect this sequence of actions during an object access are:

- *Robot cost*, i.e., the time needed for the robot arm to unload an online device and load a requested offline one (T^{robot}).
- *Head Positioning cost* (T^{head}), i.e., the delay due to the placement of the disk (tape) drive head on the appropriate disk (tape) location. In the case of disks, the positioning cost includes a *seek* (T^{head}_{seek}) to the appropriate track and *rotation* ($T^{head}_{rotation}$) to the appropriate sector of the track. In the case of tapes, the positioning cost includes only a *search* operation (T^{head}_{search}) to the appropriate tape location where the objec resides.
- *Transfer cost*, i.e., the time needed for the head to read the object ($T^{transfer}$).

When a request arrives for an object stored in the library the following events occur:

a) first the tape (or disk) that contains the requested object must be located and if it is offline it must be exchanged with an online "victim" tape. The selection of the "victim" tape (disk) is determined by a replacement algorithm. This tape exchange process takes T^{robot} seconds and depends on the particular hardware of the library while it has been found to be independent of the particular tape (or disk) that is requested each time and the distances traveled by the robot arm ([3]). Typical values for the total robot delay range from 10 to 30 seconds.

b) secondly, the tape (or disk) head locates the requested object within the tape (disk) in T^{head}_{search} (or $T^{head}_{seek} + T^{head}_{rotation}$) seconds.

c) finally, the object is read by the head in $T^{transfer}$ seconds.

The alternative placement schemes impact on some of the components of the access cost, not all of them: the transfer and the head rotation costs are always paid regardless of the placement and hence are not taken into account in the cost minimization [1]. On the contrary, T^{head}_{seek},T^{head}_{search} and T^{robot} depend on the distance traveled by the head and therefore change whenever the placement changes.

[1]Since the rotation component of the head positioning cost does not depend on the placement, the term *head positioning delay* will refer to the seek delay only.

1.1 The Problem

Accessing tertiary libraries is typically at least 3 orders of magnitude costlier than accessing secondary storage. Yet, related research has neglected the issue of optimal data placement in tertiary storage while the issue has received considerable attention for disk based secondary storage ([5],[8],[9],[1] and [10], [11]). In this paper we address optimal data placement in tertiary storage in order to minimize the expected access cost.

The access cost in disk libraries is dominated by the disk exchange operation since it takes many seconds (while head positioning takes less than 20 ms). In tape libraries both the *head positioning delay* and the *robot delay* (as defined above) participate in the estimation of the access cost. Even high-end tape library products have a seek delay of more than one second per GB.

This paper focuses on the issue of minimizing the delay of random accesses in both tape and disk libraries. We consider a disk (or tape) library consisting of N disks (tapes) and M drives and a set of O objects with different access probabilities. The access cost depends on the placement strategies that

1. determine which objects are placed onto which media and
2. determine the order with which the objects of some media are placed in it ([10]).

We show that for disk libraries only placement strategies that determine which objects are placed on which disks are relevant. For tape libraries placement strategies must solve the problem at both levels.

The paper is organized in five sections. In section (2) an overview is provided describing the mathematical tools that are used throughout the paper and which are based on the Majorization theory and the theory of Schur functions. In section (3) the optimal placement problem for single and multi-drive libraries and under different scheduling algorithms is examined and solved and optimal schemes are provided for both equi-sized and variable sized objects. In section (4) the problem is solved for tape libraries and optimal algorithms are derived for different tape library technologies. Finally, section (5) contains concluding remarks and summarizes the importance of the results.

2 Mathematical Tools

2.1 Majorization Theory and Schur Functions

Let us consider two decreasing probability vectors $\vec{\mathbf{p}} = (p_1, \ldots, p_n)$ and $\vec{\mathbf{q}} = (q_1, \ldots, q_n)$. Formally, we say that $\vec{\mathbf{p}}$ majorizes $\vec{\mathbf{q}}$, which is symbolized as $\vec{\mathbf{q}} \prec \vec{\mathbf{p}}$, if $\sum_{i=1}^{j} p_i \geq \sum_{i=1}^{j} q_i$ for all $j < n$ and $\sum_{i=1}^{n} p_i = \sum_{i=1}^{n} q_i$. Intuitively, $\vec{\mathbf{p}}$ majorizes $\vec{\mathbf{q}}$ implies that $\vec{\mathbf{p}}$ is "more skewed vector" than $\vec{\mathbf{q}}$. The concept of majorization can be used to compare the values of functions of vectors that are of a specific kind (Schur functions).

If a function $\phi : R^n \rightarrow R$ is **Schur convex** (or Schur **increasing**) and $\vec{\mathbf{p}}$ majorizes $\vec{\mathbf{q}}$, then $\phi(\vec{\mathbf{p}}) \geq \phi(\vec{\mathbf{q}})$. If a function $\phi(x)$ is a **Schur concave** (or Schur **decreasing**)

and $\vec{\mathbf{p}}$ majorizes $\vec{\mathbf{q}}$, then $\phi(\vec{\mathbf{p}}) \leq \phi(\vec{\mathbf{q}})$. Thus, it is easy to describe how a Schur function will behave for more uniform or more skewed probability distributions.

A necessary and sufficient condition for a continuously differentiable function $\phi : R^n \rightarrow R$ to be Schur convex (concave) is that for all $i \neq j$:

$$(x_i - x_j)\left(\frac{\partial \phi}{\partial x_i} - \frac{\partial \phi}{\partial x_j} \right) \geq (\leq) 0$$

where each x_i is a component of the probability density vector $\vec{\mathbf{x}} = (x_1, \ldots, x_n)$ (see for example [2]).

The following lemmas will be applied throughout the paper:

Lemma 1: *Consider λ real-valued, Schur-convex (Schur-concave) functions $\phi_i : R^n \rightarrow R$, $i = 1, \ldots, \lambda$. Then, their sum i.e. the function $F : R^n \rightarrow R$, $F = \sum_{i=1}^{\lambda} \phi_i$ is also a Schur-convex (Schur-concave) function.*

Proof

Since for all $i = 1, \ldots, \lambda$, ϕ_i is Schur-convex (Schur-concave), then for all vectors $\vec{x} \epsilon R^n$, $\vec{y} \epsilon R^n$ such that $\vec{x} \prec \vec{y}$ it holds that:

$$\begin{array}{cc} \phi_1(\vec{x}) \leq \phi_1(\vec{y}) & (\phi_1(\vec{x}) \geq \phi_1(\vec{y})) \\ \phi_2(\vec{x}) \leq \phi_2(\vec{y}) & (\phi_2(\vec{x}) \geq \phi_2(\vec{y})) \\ \vdots & \vdots \\ \phi_\lambda(\vec{x}) \leq \phi_\lambda(\vec{y}) & (\phi_\lambda(\vec{x}) \geq \phi_\lambda(\vec{y})) \end{array}$$

Adding the inequalities yields:

$$F(\vec{x}) = \sum_{i=1}^{\lambda} \phi_i(\vec{x}) \leq \sum_{i=1}^{\lambda} \phi_i(\vec{y}) = F(\vec{y}) \text{ (or } F(\vec{x}) = \sum_{i=1}^{\lambda} \phi_i(\vec{x}) \geq \sum_{i=1}^{\lambda} \phi_i(\vec{y}) = F(\vec{y}))$$

for all $\vec{x} \epsilon R^n$, $\vec{y} \epsilon R^n$ such that $\vec{x} \prec \vec{y}$. Therefore F is a Schur-convex (Schur-concave) function. □

2.2 Minimization of $\sum_j j \cdot p_j$

Lemma 2: *Let $\vec{p}, \vec{q} \epsilon \mathcal{R}^n$ be two decreasing real-valued vectors and assume that $\vec{p}$ majorizes $\vec{q}$, that is $\vec{q} \prec \vec{p}$. Then*

$$\sum_{j=1}^{n} j \cdot p_j \leq \sum_{j=1}^{n} j \cdot q_j$$

i.e. the sum of the products $j \cdot p_j$ is minimized for the most skewed vector.

Proof

Let $\vec{p} = (p_1, \ldots, p_n)$ and $\vec{q} = (q_1, \ldots, q_n)$. Since we assumed that the vectors are decreasing the following inequality holds:

$$\forall \;\; i, j, \;\; i < j \Rightarrow p_i > p_j \Rightarrow (i - j)(p_i - p_j) < 0 \tag{1}$$

Let $\phi(\vec{p}) = \sum_{i=1}^{n} i p_i$ be our objective function which must be examined in terms of minimization. The derivative of $\phi(\vec{p})$ on p_i is:

$$\frac{\partial \phi(\vec{p})}{\partial p_i} = i$$

and $\forall \;\; i, j, \;\; i < j$

$$(p_i - p_j)\left(\frac{\partial \phi(\vec{p})}{\partial p_i} - \frac{\partial \phi(\vec{p})}{\partial p_j}\right) = (p_i - p_j)(i - j) \leq 0 \tag{2}$$

The latter inequality holds because the vectors are decreasing as is showed by inequality (1). The relationship (2) is a sufficient condition for our objective function to be Schur-concave according to the theory of Majorization and the theory of Schur functions. Therefore, our objective function is minimized for the most skewed vector, i.e., if $\vec{q} \prec \vec{p}$ then $\sum_{j=1}^{n} j \cdot p_j \leq \sum_{j=1}^{n} j \cdot q_j$ $\square$

3 Disk Libraries

We have derived the cost function for a first configuration consisting of one disk drive and multiple disks and a second configuration with two disk drives and three disks. These results were based on the Majorization theory and Markov chains, respectively. A generalized configuration, including an arbitrary number of drives and disks, is also presented and an optimal placement scheme is derived. Different analysis is provided for two different request scheduling algorithms: FCFS and Bypass scheduling.

3.1 Problem Definition

Let D denote the number of disk drives in our system and T be the total number of disks. The disks have identical storage and functional characteristics. The identical storage characteristics mean that all disks have the same storage capacity which is denoted as C (bits). The functional characteristics refer to the disk operations such as the data transfer rate and the positioning (seek and rotational) delays. Since the latter are the same for all disks, the access cost within each disk is the same regardless of the particular disk that is involved in the access operation.

There are O objects in total each having access probability q_i, $i = 1, \ldots, O$, that must be placed onto the T identical disks of the library. We assume that each object

must be uniquely mapped in the library and that no replication of objects is allowed. We also assume a steady system state in which all drives are loaded, either being idle or not. Since the disks have equal capacities, the number K^i of objects stored per disk, depends on whether the objects have the same length or not. In the case that all objects have size equal to Z bits, each disk can hold $K = \lfloor \frac{C}{Z} \rfloor$ objects. Thus, each disk can be thought of as containing K separate storage locations, with one storage location for each object. Let d^i denote the i^{th} disk of the library ($i = 1, \ldots, T$) and l^i_j be the the j^{th} storage location within the i^{th} disk d^i.

Table 1 summarizes the parameters of our system. We denote p^i_j the probability

D	number of drives in the system.
T	number of disks in the system.
O	number of objects that must be placed on disks.
K^i	number of objects stored in the i^{th} disk.
Z_i	the size of the i^{th} object.
C	disk capacity (bytes), assumed to be equal for all disks.
l_j	the j^{th} location within any disk.
d^i	the i^{th} disk of the library.
l^i_j	the j^{th} location within the i^{th} disk.
q_i	access probability of the i^{th} object.
p^i	cumulative probability of the i^{th} disk.
p_j	cumulative probability of the j^{th} objects in all T disks.
p^i_j	access probability of the j^{th} object stored in the i^{th} disk.
$\vec{P^r}$	$(p^1, \ldots, p^T)$ row probabilities.
$\vec{P_c}$	$(p_1, \ldots, p_K)$ column probabilities.
$\vec{P^i}$	$(p^i_1, \ldots, p^i_{K_i})$ probabilities of i^{th} tape.
$\vec{P_j}$	$(p^1_j, \ldots, p^T_j)$ probabilities of j^{th} column.

Table 1: The parameters of our system.

that the object stored at location l^i_j is requested. The cumulative probability p^i that a disk d^i is requested is the probability that any of the objects stored on disk d^i is requested and it is equal to the sum of these probabilities:

$$p^i = \sum_{j=1}^{K} p^i_j \tag{3}$$

We define p_j to be the cumulative probability that an object stored at any of the l_j locations of the T disks is requested. The probability p_j is equal to the sum of these probabilities:

$$p_j = \sum_{i=1}^{T} p^i_j \tag{4}$$

The disks of the library can be viewed as a 2-dimensional array $d : \epsilon T \times K$, such that $d[i][j] = l^i_j$, for all $i = 1, \ldots, T$, $j = 1, \ldots, K$. Then we can define the vector

consisting of the row probabilities $\vec{P^r} = (p^1, \ldots, p^T)$ and the vector consisting of the column probabilities $\vec{P_c} = (p_1, \ldots, p_K)$ of the array.

We wish to determine the optimal placement of the O objects onto the $T \cdot K$ storage locations of the disk library. This placement problem can be viewed as a two-level problem:

- at the first level of the problem, the contents of each disk are determined, i.e., which objects must be placed onto which disk.
- at the second level of the problem, given the objects to be placed within each disk the precise mapping of these objects to the storage locations of the disk is required, i.e., which objects go to which disk locations.

For disk libraries, the expression "placement problem" refers to the first level problem of allocating objects to disks. As for the second level problem the related literature (see [1], [5], [8]) provides various solutions.

We characterize as optimal the placement scheme which results in the minimum expected number of disk exchanges for a random request.

We should note that there are two factors that affect the minimization of the disk exchange cost:

a) the placement strategy itself of the O objects across the T disks.

b) the algorithm employed in selecting the next disk to load (i.e., given a number of requests in a queue waiting for tertiary storage service, which request will be selected for service next and hence which one of the referenced disks will be loaded next.)

3.2 Disk Library with a Single Drive

Let us first consider the case of $D = 1$ and $T > 1$, that is, there is only one disk drive in the system, and many disks. This means, that each time only one from the T disks can be on-line. We will first try to minimize the access cost $C_{disk}^{(1)}$ when there is only one drive.

3.2.1 Optimal Placement with FCFS Scheduling

The access cost $C_{disk}^{(1)}$ is the expected disk exchange delay that is caused by a random request. Let $T_{exchange}$ be the time taken for an on-line disk to be removed from its drive and be replaced by an off-line disk. $T_{exchange}$ is independent from the relative position of disks on the shelves ([3]).

Let $p_{exchange}$ be the probability that a disk exchange is triggered by a random request. Then:

$$p_{exchange} = \sum_{i=1}^{T} p^i (1 - p^i) \tag{5}$$

The product p^i(1–p^i) is the probability that the disk d^i is requested (which occurs with probability p^i) and it is not on-line because the previous request had not requested it

(which occurs with probability $(1-p^i)$). The summation over all disks expresses the fact that the requested disk may be any one of the $T-1$ disks in the shelves.

The expected disk exchange delay is:

$$C_{disk}^{(1)}(\vec{P}^r) = T_{exchange} \cdot p_{exchange} = T_{exchange} \sum_{i=1}^{T} p^i(1-p^i) \tag{6}$$

Theorem 1: *Function $C_{disk}^{(1)}(\vec{P}^r)$ is Schur concave. In other words,*

$$(p_i - p_j)\left(\frac{\partial C_{disk}^{(1)}}{\partial p_i} - \frac{\partial C_{disk}^{(1)}}{\partial p_j} \right) \leq 0$$

Proof

In our case, the partial derivative of the cost function $p^i(1-p^i)$ on p^i is calculated to be:

$$\frac{\partial C_{disk}^{(1)}}{\partial p^i} = \frac{\partial (p^i - {p^i}^2)}{\partial p^i} = 1 - 2p^i \tag{7}$$

The product that needs to be evaluated to determine if a function is concave, can be calculated for our cost function by substituting the derivative of the cost as follows:

$$(p^i - p^j)\left(\frac{\partial C_{disk}^{(1)}}{\partial p^i} - \frac{\partial C_{disk}^{(1)}}{\partial p^j} \right) = (p^i - p^j)[(1-2p^i) - (1-2p^j)] = 2(p^i - p^j)(p^j - p^i) \leq 0$$

The above equation holds for all i, j.

□

This result is interpreted as follows: since the row probability vector $\vec{P}^r \epsilon R^T$ has as components the cumulative probabilities of the disks ($\vec{P}^r = (p^1, \ldots, p^T)$), if S_1, S_2 are two different placement schemes which result in the row probability vectors $\vec{P}^{r1}$, $\vec{P}^{r2}$ and $\vec{P}^{r1} \prec \vec{P}^{r2}$, then the cost function is minimized when placement S_2 is enforced. This is true, since the row probability vector which is produced by S_2 majorizes the corresponding vector of S_1 scheme and thus $C_{disk}^{(1)}(\vec{P}^{r2}) < C_{disk}^{(1)}(\vec{P}^{r1})$. The optimal placement scheme S_{opt} is then the scheme with row vector $\vec{P}_{opt}^r$ such that $\vec{P}^r \prec \vec{P}_{opt}^r$ where $\vec{P}^r$ is the row vector that any placement scheme other than S_{opt} produces. In other words, we must place the objects in the disks in such a way that the resulting row vector majorizes all other possible row vectors. Such an optimal placement algorithm is presented below.

Optimal Placement Algorithm

Initialize FreeDisks to include all system disks: FreeDisks=($d^1, \ldots, d^T$).
Initialize UnallocatedObjects to include all system objects: UnallocatedObjects=($O_1, \ldots, O_O$).
Set d^{next} to d^1.
while *UnallocatedObjects and FreeDisks sets are not empty* **do**
begin
Select from the set UnallocatedObjects those K objects that have the maximum cumulative probability
Place the selected objects on disk d^{next}.

Remove the selected objects from the set UnallocatedObjects.
Remove disk D_i from the set FreeDisks.
Set d^{next} to d^{next+1}.
end

3.2.2 Optimal Placement with Bypass Scheduling

So far we have assumed that requests are serviced with First Come First Served (FCFS) scheduling. FCFS scheduling is fair for all requests and simple to implement but different alternatives of request scheduling which take advantage of the on-line disk are likely to perform better.

Bypass scheduling is such a sophisticated scheduling policy. It gives highest priority to all the pending requests in the queue that reference the on-line disk regardless of the arrival times of the requests. That is, if the i^{th} disk is on-line, all the requests in the queue that hit d^i are serviced next. The disk d^i is replaced only when there is no unserviced request for it in the queue. The new disk d^j that will eventually replace d^i might be any one of the disks that are referenced by one or more requests of the queue.

Assume that the queue of pending requests contains N unserviced requests for any of the T disks of the library and the drive of the system is loaded with a disk d^i. Let R be the set of all these pending requests. Then, we define the *reference set $R^j \subseteq R$ of disk d^j* to be the set of pending requests that hit disk d^j. If X such non-empty different sets exist in the queue then the number of disk exchanges will be X if the reference set R^i of the on-line disk is empty, otherwise it will be $X-1$. This means that the expected number of disk exchanges to service the N requests in the queue is equal to the expected number of different reference sets that exist in the queue:

$$\mathrm{E\,(no\,of\,disk\,exchanges)} = \mathrm{E\,(no\,of\,non\,empty\,reference\,sets)} = \sum_{\mathrm{i=1}}^{\mathrm{T}} \left(1 - (1 - \mathrm{p^i})^{\mathrm{N}}\right) \qquad (8)$$

The i^{th} term $1-(1-p^i)^N$ in the summation is the probability [1] that one or more requests hitting the disk d^i have entered the queue or, in other words, the probability that the reference set R^i of disk d^i is non-empty. Recalling that the definition of the access cost is the product of the expected number of disk exchanges times the average delay of a disk exchange $T_{exchange}$, we can derive the access cost $C^{(1)}_{bypass}$ when bypass scheduling is employed:

$$C^{(1)}_{bypass} = T_{exchange} * \mathrm{E\,(no\,of\,disk\,exchanges)} \qquad (9)$$

or substituting the expected number of disk exchanges from equation (8):

$$C^{(1)}_{bypass} = T_{exchange} * \sum_{i=1}^{T} \left(1 - (1 - p^i)^N\right) = T_{exchange} * \left(T - \sum_{i=1}^{T} (1 - p^i)^N\right) \qquad (10)$$

[1] A selection with replacement modeling is clearly suitable for our system.

The access cost of equation (10) is then our cost function which will be examined for minimization. In particular, we will determine the distribution of the probability vector $\vec{P}^r = (p^1, \ldots, p^T)$ which minimizes our cost function.

Theorem 2

The function $\phi(\vec{P}^r) = \sum_{i=1}^{T} (1-p^i)^N$ is Schur-convex.

Proof

Differentiating ϕ with respect to p^i we obtain:

$$\frac{\partial \phi}{\partial p^i} = -N(1-p^i)^{N-1} \tag{11}$$

For all $p^i \neq p^j$ we have:

$$(p^i - p^j)\left(\frac{\partial \phi}{\partial p^i} - \frac{\partial \phi}{\partial p^j}\right) = (p^i - p^j)\left(-N(1-p^i)^{N-1} + N(1-p^j)^{N-1}\right) > 0 \tag{12}$$

We can verify that if for example $p^i < p^j$ then: $1-p^i > 1-p^j \Leftrightarrow N(1-p^i)^{N-1} > N(1-p^j)^{N-1} \Leftrightarrow N(1-p^j)^{N-1} - N(1-p^i)^{N-1} < 0$
□.
According to equation (10) the cost is minimized when the function $\phi(\vec{P}^r) = \sum_{i=1}^{T} (1-p^i)^N$ is maximized. This occurs when the placement is such, that the probabilities distributed across all T disks compose a $\vec{P}^R_{opt}$ vector which majorizes the vector of any other placement scheme since according to the above theorem $\phi(\vec{P}^r)$ is Schur convex. This result is the same as the one that we proved for the case of FCFS scheduling of requests. Therefore, the optimal placement algorithm for Bypass scheduling is the same to the algorithm that we provided for the case of FCFS scheduling of requests.

3.2.3 Optimal Placement of Variable Sized Objects

We will now examine the problem with objects of variable sizes.

3.2.3.1 Objects with the Same Access Probability

Let the O objects have equal access probabilities, $q_l = \frac{1}{O}, (l = 1, \ldots, O)$ and that K^i is the number of objects placed on the i^{th} disk by a random placement scheme. The aggregate probability p^i of the i^{th} disk is then:

$$p^i = \frac{K^i}{O} \tag{13}$$

The probability of a disk exchange (and hence the cost function C) is then:

$$P_{exchange} = C = \sum_{i=1}^{T} p^i(1-p^i) = \sum_{i=1}^{T} \frac{K^i}{O}\left(1 - \frac{K^i}{O}\right) \tag{14}$$

We will compute the exchange cost for all possible disk population vectors $\vec{\mathbf{K}} = (K^1, \ldots, K^T)$ and determine the one with the minimum cost.

Theorem 3

The function $\phi(\vec{K}) = \sum_{i=1}^{T} \frac{K^i}{O}\left(1 - \frac{K^i}{O}\right)$ is Schur-concave.

Proof

The derivative of $\phi(\vec{K})$ on K_i is:

$$\frac{\partial \phi(\vec{K})}{\partial K^i} = \frac{1}{O} - \frac{2\,K^i}{O^2} \tag{15}$$

and

$$\begin{aligned}(K^i - K^j)\left(\frac{\partial \phi(\vec{K})}{\partial K^i} - \frac{\partial \phi(\vec{K})}{\partial K^j}\right) &= (K^i - K^j)\left(\frac{1}{O} - \frac{2\,K^i}{O^2} - \frac{1}{O} + \frac{2\,K^j}{O^2}\right) \\ &= \frac{2}{O^2}(K^i - K^j)(K^j - K^i) < 0\end{aligned} \tag{16}$$

The latter inequality holds always for all $K^i \neq K^j$.

□

Therefore, the optimal placement scheme should allocate objects to disks, so that the resulting disk population vector $\vec{K} = (K^1, \ldots, K^T)$ majorizes the vector of any other placement scheme.

In particular, the optimal placement algorithm should operate as follows:

a) Sort the objects in increasing size order.

b) Starting at the beginning, place as many objects as can fit in the first disk.

c) Remove these objects from the list of unallocated objects.

d) Repeat (b) for all disks and objects left until either the list of unallocated objects is empty or no space is left on the devices.

3.2.3.2 Objects with Variable Access Probability

In this section, we will study the optimal placement of objects that have both different sizes and different access probabilities.

We assume that each object has probability q_l to be accessed and that its size is z_l bits ($l = 1, \ldots, O$). Let K^i ($i = 1, \ldots, T$) be the number of objects that are allocated to disk d^i by a random placement policy. The cumulative probability of the objects allocated to disk d^i is the probability p^i of accessing disk d^i:

$$p^i = \sum_{j=1}^{K^i} p_j^i \quad \forall\, i = 1, \ldots, T \tag{17}$$

and the expected number of disk exchanges is:

$$C = \sum_{i=1}^{T} p^i(1 - p^i) \tag{18}$$

where the $p^i s$ are given by (17). The summation of (18) has been shown in Theorem 1 to be minimal when the vector $\vec{P}^r$ of the $p^i s$ majorizes all others. In our case, $\vec{P}^r = (p^1, \ldots, p^T) = \left(\sum_{j=1}^{K^1} p_j^1, \ldots, \sum_{j=1}^{K^T} p_j^T \right)$.

In other words, if an algorithm can place the objects onto the disks, so that the resulting $\vec{P}^r_{opt}$ majorizes the $\vec{P}^r$ vector of any other placement scheme, then this algorithm has accomplished the minimum number of disk exchanges and thus it is optimal.

For equi-sized objects it was sufficient to accumulate as big a probability as possible onto the first disk, then onto the second and so on. The objective is the same in this case as well, i.e. for each disk we must accumulate the biggest probability possible from the objects left and allocate it to the disk. However, since the object sizes vary, the algorithm should take them into consideration. The construction of the most skewed vector $\vec{P}^r_{opt}$ is reducible to the well-known knapsack problem of the algorithmic literature ([12]) which has been solved with dynamic programming. In addition, we have constructed an efficient heuristic algorithm which determines the placement of variable-sized objects within the disk library in polynomial time. The heuristic algorithm is omitted due to space limitations but can be found in ([4]).

3.3 Multiple Disk Drive Configuration

We now study a system with multiple disk drives and multiple disks. We define the probability $p^{(i,j)}$ such that:

$$p^{(i,j)} : \text{probability that the } i \text{ and } j \text{ disks are on-line} \quad \text{for } i, j = 1, \ldots, T$$

Furthermore, we assume that the row probability vector $\vec{P}^R = (p_1, p_2, \ldots, p_T)$ is increasing, i.e.,

$$p^1 < p^2 < \ldots < p^T \tag{19}$$

That is, without loss of generality we assume an ordering of disks according to their popularity, such that for any $1 \leq i < j \leq T$, $p^i < p^j$ holds. Among the placement algorithms which produce an increasing [1] $\vec{P}^R$ vector we will determine the one with the minimum cost.

3.3.1 Disk Replacement Algorithm

The scheme that is proposed below is based on the assumption that when a *miss* occurs (i.e., a request refers to a disk that is off-line), a disk replacement algorithm is employed which, based on the popularity of disks (how frequently the disks were accessed in the past), decides to replace the on-line disk with the smallest probability of access. In other words, if d^i, d^j are on-line and idle when a miss occurs, the i^{th} disk is replaced and exchanged with the desired disk. This replacement algorithm that we employ is called the **Least Popular Disk Replacement Algorithm (LPR)**. In the following sections we will derive a placement strategy such that when combined with the LPR the average access cost is minimized.

[1] The fact that we consider placements with increasing $\vec{P}^R$ is not limiting. The same results are obtained when considering all placements with decreasing $\vec{P}^R$.

3.3.2 Access Cost Minimization for the Case of Two Disk Drives and Three Disks

We first concentrate on a restricted example where $D=2$ drives and $T=3$ disks while in the following section a generalized optimal placement scheme for an arbitrary number of disks and drives will be derived.

Since $D = 2$ and $T = 3$ the row probability vector is $\vec{P}^R = (p^1, p^2, p^3)$ with $p^1 < p^2 < p^3$. Figure (1) shows the corresponding Markov chain state diagram. The arrows show transitions among the states along with the probability of occurrence of the transition.

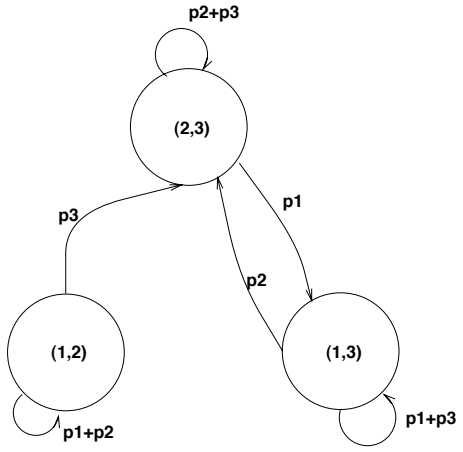

Figure 1: Diagram of Markov-chains for 2 drives and 3 disks ($p^1 < p^2 < p^3$).

The node labeled (i, j) represents a system state, in which disks i and j are on-line. The Markov chain contains a *closed subset of states*, namely, $\{(2,3), (1,3)\}$, since no one-step transition from any of the states in the subset to state $(1,2)$ is possible. Therefore, the Markov chain is reducible. The probabilities $p^{(1,3)}, p^{(2,3)}$ can be calculated by solving the system:

$$\begin{aligned} p^{(2,3)} &= p^{(1,3)} * p^2 + p^{(2,3)} * (p^2 + p^3) \\ p^{(1,3)} &= p^{(2,3)} * p^1 + p^{(1,3)} * (p^1 + p^3) \\ p^{(1,3)} + p^{(2,3)} &= 1 \end{aligned} \tag{20}$$

Thus,

$$p^{(1,3)} = \frac{p^1}{p^1 + p^2} \qquad p^{(2,3)} = \frac{p^2}{p^1 + p^2} \tag{21}$$

Now the exchange cost is given by:

$$C_{disk}^{(D)} = p^{(2,3)} * p^1 + p^{(1,3)} * p^2 \Leftrightarrow \tag{22}$$

$$C_{disk}^{(D)} = \frac{p^2}{(p^1 + p^2)} * p^1 + \frac{p^1}{(p^1 + p^2)} * p^2 = \frac{1}{(p^1 + p^2)} * \left(p^1 * p^2 + p^1 * p^2\right) = \frac{2p^1 p^2}{(p^1 + p^2)} \tag{23}$$

Theorem 4: The function $C_{disk}^{(D)}(\vec{P}^r)$ is Schur concave.

Proof

It can be easily verified that the partial derivative of the latter cost function is:

$$\frac{\partial C_{disk}^{(D)}}{\partial p^1} = \frac{2(p^2)^2}{(p^1+p^2)^2} \tag{24}$$

The Schur condition for concavity is:

$$\begin{aligned}(p^1-p^2)(\frac{\partial C_{disk}^{(D)}}{\partial p^1}-\frac{\partial C_{disk}^{(D)}}{\partial p^2}) &= (p^1-p^2)*\left(\frac{2(p^2)^2}{(p^1+p^2)^2}-\frac{2(p^1)^2}{(p^1+p^2)^2}\right) \\ &= \frac{2(p^1+p^2)}{(p^1+p^2)^2}(p^1-p^2)(p^2-p^1)\leq 0\end{aligned} \tag{25}$$

for all $p^1 \neq p^2$.

□

Therefore, our cost function is minimized when the row probability vector $\vec{P}^R$ is the one that majorizes all other possible vectors that correspond to other placement schemes of the same objects. The optimal placement algorithm therefore, places the objects so that the resulting $\vec{P}_{opt}^R$ majorizes the row vector $\vec{P}^R$ that any other placement produces. This placement policy is combined with the replacement algorithm, which maintains the p^3 disk always on-line on the first drive, and switches between the p^1 and p^2 disks on the second drive.

Intuitively, this replacement policy has as result that the disk with the highest probability remains on-line, in the steady system state, continuously. This is why the Markov chain is reducible. In the steady state therefore, the system behaves as if it had one on-line disk drive and two disks to be exchanged, and therefore it behaves like the one-on-line drive system.

3.3.2.1 Generalizing the Cost Derivation for T disks and D drives

These results can naturally be expanded to apply to more general configurations of D drives and $T > D$ disks. The corresponding Markov chain will also contain a subset of closed states and will be reducible. In the steady system state, the D–1 drives will be continuously occupied by the D–1 disks with the highest probabilities. The one drive left will be used to keep one of the $T-D+1$ remaining disks. Hence, the optimal placement policy, continues to place the probabilities in such a way that the resulting $\vec{P}^R$ vector majorizes all others and combines this scheme with the replacement policy which maintains the $D-1$ most popular disks active always, and performs exchanges in the one remaining disk drive. Such a policy minimizes disk exchanges due to the skewed arrangement of the probabilities within disks.

4 Tape Libraries

The factors that influence the estimation of the cost of accessing the tape objects are the *head positioning delay* and the *robot delay*. The *head delay* that is associated with an object access is attributed to two factors: a) the *search delay*, which is the time taken by the head in order to locate the requested object within the tape, and b) perhaps, the *rewind delay*, which is the time taken for the tape to perform the rewind operation. Thus,

$$head\ \ delay = search\ \ delay + rewind\ \ delay \tag{26}$$

The *robot delay* is the delay introduced when a loaded tape is removed from its tape drive and placed on the shelf and an off-line tape containing the newly requested object is subsequently placed on that particular drive.

Given current technology, two alternatives exist for the estimation of the access cost:

1. Only the head delay can be taken into account in the cost determination.

   This is meaningful for environments where the robot delay is negligible as compared to the head delay and can therefore be ignored in the cost calculations with negligible error. Such an environment could for example be the AMPEX DST series tape library systems with tape capacities up to 165 GB, search speed equal to 800 MB/sec and resulting average search time of approximately 100 sec. The latter value of the head delay is dominant when compared to the typical value of the robot delay which is reported to be less than 6 sec.

2. Both the head delay and the robot delay contribute to the cost determination.

   This is the case of tape library systems where both the robot and the head delay contribute significantly and must therefore both participate in the cost calculations. The AMPEX DST 810 with catridge capacity 3 GB is such an example. In this environment, the average search time is 1.5-2.0 sec which is smaller than the robot delay. Hence, exchanges must also be considered in the cost derivation.

Furthermore, the determination of the access cost can vary depending on the operational characteristics of the devices. One key issue is the rewind operation. Two alternatives are currently supported:

- In some technologies tape drives must essentially rewind to the PBOT [1], before being ejected ([7], [6]). This is the case for example for the Exabyte tapes. In the Ampex DST series this feature of rewinding to the physical beginning of a tape before eject is only optional.

- Other tape drives, such as the AMPEX DST series define "zones" at multiple locations along the tape, enabling rewind to proceed alternatively to any of the zones ([6]) before ejection. Most frequently, the zone nearest to the head is selected in order to minimize rewind time.

[1] Physical Beginning of Tape.

4.1 Problem Formulation

The following table summarizes the notations that are used throughout the section:

O	number of objects that must be stored in the library
K	number of objects stored per tape
D	number of tape drives
T	number of tapes
Z	size of each object (in bits)
t^i	the i^{th} tape $i = 1, \ldots, T$
l_j	the j^{th} object location within any tape
l_j^i	the j^{th} object location within the i^{th} tape t^i
p_j^i	access probability of the object stored at location l_j^i
q_k	access probability of the k^{th} object $(k = 1, \ldots, O)$
p^i	probability that one of the objects stored in tape t^i is requested $P^i = \sum_{j=1}^{K} p_j^i$
p_j	probability that one of the objects residing at location l_j of all T tapes is requested $P_j = \sum_{i=1}^{T} p_j^i$
$\vec{P^r}$	$(p^1, \ldots, p^T)$ row probabilities.
$\vec{P_c}$	$(p_1, \ldots, p_K)$ column probabilities.
$\vec{P^i}$	$(p_1^i, \ldots, p_{K_i}^i)$ probabilities of i^{th} tape.
$\vec{P_j}$	$(p_j^1, \ldots, p_j^T)$ probabilities of j^{th} column.

We are interested in determining the optimal placement of the $T{\cdot}K$ objects across all $T{\cdot}K$ possible locations of the T tapes [1]. Optimality of placement is achieved when the expected delay of accessing a random object is minimized.

We consider tapes with dominant head delay and therefore the cost function is equal to the expected head delay incurred in a random access. The case when both the robot and the head delay contribute in the access cost is studied in ([4]). According to the definition of the head delay (26), our cost function is the summation of the search and the rewind delay. Let the average search speed of the tape head be $SchSp$, and let $RwSp$ be the average rewind speed. Let also d_{search} be the expected distance (in number of bits) traveled by the head with $SchSp$ to reach a desired tape location. Then, our cost function will be the summation of $\frac{d_{search}}{SchSp}$ (search delay) plus $\frac{d_{search}}{RwSp}$ (rewind delay). In general $RwSp > SchSp$. Thus, if Rwf, $1 < Rwf < 2$ is a constant such that $(Rwf)\frac{d_{search}}{SchSp} = \frac{d_{search}}{SchSp} + \frac{d_{search}}{RwSp}$ then our cost function is:

$$AccCst = (Rwf)\,(d_{search}/SchSp) \tag{27}$$

[1] We assume that the number of object locations across all tapes and the number of objects that need to be placed in them are equal. We also assume that each object is uniquely mapped in the library and that no replication of objects is allowed. Furthermore, the system is in a steady state i.e., all drives are loaded, either being idle or not.

Since $SchSp$ and Rwf are constant the cost function depends only on the expected value of the distance of the requested object from the current head position (d_{search}).

As explained before, the current tape technology supports two alternatives for tape rewinding. Naturally, the methodology of estimating the cost of a random tape access and the corresponding optimal placement algorithm differ depending on the tape rewinding technology, since the search distances are different for different rewinding technologies. Section (4.2) provides the cost analysis and the optimal scheme for tapes which rewind to the nearest zone, while section (4.3) examines tapes which rewind to the PBOT. Both analyses are then further specialized in two cases for FIFO and SCAN ([4]) scheduling algorithms which represent systems under light and heavy load, respectively.

We should note that similar optimal placement problems with disks have been examined and solved. In [5] the optimal placement of objects within a magnetic disk in order to optimize the random access cost is proved to be the organ-pipe arrangement. The organ-pipe arrangement of a set of n probabilities $p_1, \ldots, p_n$ places the largest p_i at the middle point. Then, it repetitively places the next largest p_i, alternating between the position immediately to the left (right) of those already placed and the position immediately to the right (left). Similar placement algorithms have been developed for CLV disks ([8]) and multi-zoned CAV disks ([9]).

4.2 Tapes that Rewind to the Nearest Zone.

We examine tapes which enable tape rewinding to the nearest tape zone as opposed to tapes which require to be rewound to their physical beginning before they can be ejected. Cost analysis is different depending on the request scheduling policy. Therefore, we have separately examined the cases of FCFS and Scan scheduling which are the most efficient for lightly and heavily loaded systems respectively and have derived optimal placement algorithms. In the following, we present the cost analysis and the optimal placement for FCFS scheduling only, due to space limitations. Detailed analysis and results for Scan scheduling are included in our complete paper ([4]).

4.2.1 Placement of Objects within a Tape

The cost function for a single tape is the expected distance that must be traveled by the tape head in order to serve a random request for an object of this tape and it is derived as follows: let l_w^i and l_z^i be two locations within a random tape t^i. Assume that l_w^i is the current head location (i.e., the location of the object that was previously requested from t^i) and l_z^i is the location where the head must be moved to access the object of the next request for t^i. The distance $d_{search}(l_w^i \rightarrow l_z^i)$ that must be traveled is then:

$$d_{search}(l_w^i \rightarrow l_z^i) = \begin{cases} (w - z + 1)Z, & \text{, if } w > z \\ (z - w - 1)Z, & \text{, if } w < z \\ 0, & \text{, if } w = z \end{cases} \quad (28)$$

The definition of $d_{search}(l_w^i \rightarrow l_z^i)$ is such that the distance when moving from the tape location l_w^i to l_{w+1}^i is 0, while the distance when moving from the tape location l_w^i to location l_{w-1}^i is $2\,Z$.

The expected distance d_{search}^i that must be traveled within t^i to serve a random request that hits t^i is derived by summing the distances of all possible events of moving between any l_w^i, l_z^i tape locations:

$$\begin{aligned} d_{search}^i &= \sum_{w<z} p_w^i p_z^i (z-w-1)Z + \sum_{w>z} p_w^i p_z^i (w-z+1)Z \\ &= \sum_{w,z} p_w^i p_z^i \left|w-z\right| Z - Z \sum_{w<z} p_w^i p_z^i + Z \sum_{w>z} p_w^i p_z^i \\ &= \sum_{w,z} p_w^i p_z^i \left|w-z\right| Z + Z \sum_{w} \left(p_w^i\right)^2 \end{aligned} \tag{29}$$

In the search distance function the term $Z \sum_{w} \left(p_w^i\right)^2$ is independent from the relative placement of probabilities within the tape. Therefore, the only relevant distance component is $\sum_{(w,z)} p_w^i p_z^i \left|w-z\right| Z$. This is exactly the cost function that must be minimized when considering the traditional problem of placing objects on a disk. Wong has shown ([5]) that this function is minimized when objects are placed in an organ pipe arrangement. Therefore, given the information about which objects must be placed on which tape, the optimal placement of objects within each tape is the one that performs an organ-pipe arrangement of the probabilities.

4.2.2 Assignment of Objects to Tapes

We are now left with the problem of optimally determining the contents of each tape, i.e., how much aggregate probability must be allocated to each tape. The cost function is the expected total distance d_{search} traveled within all tapes when each of the tapes serves a random request for one of the objects that it holds. In other words, the cost function is $d_{search} = \sum_{i=1}^{T} d_{search}^i$ or from equation (29)

$$d_{search} = \sum_{i=1}^{T} \left(\sum_{w,z} p_w^i p_z^i \left|w-z\right| Z + Z \sum_{w} \left(p_w^i\right)^2 \right) \tag{30}$$

and

$$\sum_{i=1}^{T} \sum_{w,z} p_w^i p_z^i \left|w-z\right| = \sum_{w,z} \left(\sum_{i=1}^{T} p_w^i p_z^i \ \left|w-z\right| \right) = \sum_{w,z} \left|w-z\right| \left(\sum_{i=1}^{T} p_w^i p_z^i \right) \tag{31}$$

Theorem 5: The function $\phi(\vec{P}_w) = \sum_{i=1}^{T} p_w^i p_z^i$ is Schur convex for all $w = 1, \ldots, K$ and it is minimized when the column vectors $\vec{P}_w$ are as uniform as possible for all $w = 1, \ldots, K$.

Proof

Differentiating we get $\frac{\partial \phi(\vec{P}_w)}{\partial p_w^i} = p_z^i$ and $\frac{\partial \phi(\vec{P}_w)}{\partial p_w^m} = p_z^m$. Assuming, for example, decreasing column vectors [1] it holds that for all $i < m$, $p_w^i > p_w^m$, $p_z^i > p_z^m$ and therefore $(p_w^i - p_w^m)(p_z^i - p_z^m) > 0$. Thus, $\phi(\vec{P}_w)$ is Schur convex.
□.
Therefore, for each column vector $\vec{P}_w = (p_w^1, p_w^2, \ldots, p_w^T)$ the sum $\sum_{i=1}^{T} p_w^i p_z^i$ is minimum when the vector $\vec{P}_w = (p_w^1, p_w^2, \ldots, p_w^T)$ is majorized by all other possible vectors (i.e., has as equal components as possible).

A consequence of the "$\vec{P}_w$ uniform" optimality condition that we just derived is the placement the biggest probabilities in the middle locations of each tape. Since we have shown that within each tape the organ pipe placement is optimal we know that the q_1 probability (assuming $q_1 > q_2 > \ldots > q_O$) will be placed in the middle location of one tape say in $t^i_{\frac{K}{2}}$ for $1 \leq i \leq T$. Then, the only way to produce the most uniform $\vec{P}_{\frac{K}{2}}$ column vector is to fill the rest of its components with $q_2, \ldots, q_T$. Thus, I will have the T most popular objects in the middle location of each tape. The same holds for the rest of the tapes and objects.

The optimal placement scheme is shown in figure (2) for a library consisting of 3 tapes assuming that each tape can hold 5 equi-sized objects that have different access probabilities.

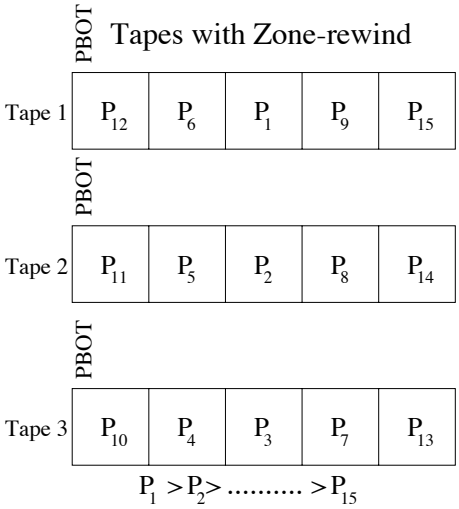

Figure 2: Optimal placement

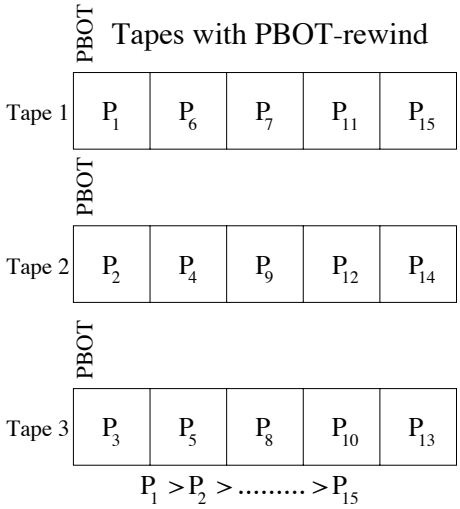

Figure 3: Optimal placement

4.3 Tapes that Rewind to the PBOT

In this section, we examine tapes which always rewind to their beginning before being ejected. As we have already mentioned the analysis is different depending on

[1] The fact that we consider placements with decreasing column vectors is not limiting. The same results are obtained when considering all placements which result in increasing columns. Our objective is to determine the placement with the minimum cost among the all placements which produce decreasing columns.

the request scheduling policy. In the following, we derive the optimal placement for systems with FCFS scheduling while the analysis for SCAN scheduling can be found in ([4]).

Let t^i be a single online tape and assume that the j^{th} object of that tape is requested. The distance $d_{search}(l_1^i \rightarrow l_j^i)$ that will be traveled by the head during searching for the j^{th} object is equal to the total space occupied by the $j-1$ objects that are placed in front of the requested object:

$$d_{search}(l_1^i \rightarrow l_j^i) = \sum_{l=1}^{j} Z = (j-1)Z \tag{32}$$

assuming that the initial head position is at the PBOT (i.e., location l_1^i). The expected distance for randomly accessing any of the K objects located on the tape t^i is d_{search}^i:

$$d_{search}^i = Z\left(\sum_{j=1}^{K} j \cdot p_j^i - \sum_{j=1}^{K} p_j^i\right) \tag{33}$$

The cost function d_{search} is the sum of the expected distances traveled in all T tapes in order for each tape to serve a request for a random object on the tape:

$$d_{search} = \sum_{i=1}^{T} Z \cdot \left(\sum_{j=1}^{K} j \cdot p_j^i - \sum_{j=1}^{K} p_j^i\right) \tag{34}$$

which can be simplified as follows:

$$\begin{aligned} d_{search} &= Z \cdot \sum_{i=1}^{T}\sum_{j=1}^{K} j \cdot p_j^i - \sum_{i=1}^{T}\sum_{j=1}^{K} Z \cdot p_j^i \\ &= Z \cdot \sum_{i=1}^{T}\sum_{j=1}^{K} j \cdot p_j^i - Z \end{aligned} \tag{35}$$

If we set $p_j = \sum_{i=1}^{T} p_j^i$ then p_j expresses the probability that one of the j^{th} objects of the T tapes is requested and equation (35) can be rewritten as follows:

$$d_{search} = Z \cdot \sum_{j=1}^{K} j \cdot p_j - Z \tag{36}$$

The expected distance of equation (36) and hence our cost function is minimized when the summation $\sum_{j=1}^{K} j \cdot p_j$ is minimized. Consider the column vector $\vec{P}_c = (p_1, \ldots, p_K)$ in which the component p_j is the aggregate access probability of the objects stored at location l_j^i of all tapes. As we have proved in Lemma 2 the summation $\sum_j j \cdot p_j$ is minimized when when the vector $\vec{P}_c$ majorizes all others (i.e., is as skewed as possible). The optimal placement scheme must therefore arrange the objects within the tapes so that the resulting $\vec{P}_c$ vector is as skewed as possible. One such scheme for example, is the one which stores each of the T most popular objects first in each of the T tapes, each of the next T most popular objects second in each of the tapes and so on.

An Optimal Placement Algorithm for Lightly Loaded Systems with Rewind to PBOT.

Sort the UnallocatedObjects in decreasing probability order.
while *the set UnallocatedObjects is not empty* **do**
begin
Scatter randomly the first T objects of the set UnallocatedObjects onto the first free location of each of the T tapes.
Remove the first T objects from the set UnallocatedObjects.
end

The optimal placement is depicted in figure (3) for a simple case of 15 objects with different access probabilities that are allocated onto the 3 tapes (each tape holding 5 objects) of a tape library.

5 Summary

In this paper, we studied the problem of data placement in disk and tape libraries. This problem is important since tertiary storage is much slower to access than secondary storage.

In the case of disk libraries with one on-line drive the major cost to be optimized is the expected number of disk exchanges, since each disk exchange costs somewhere between 5 and 15 seconds. (To find the data on the on-line disk is much less expensive due to the random access mechanism of disks). We showed using the theory of Majorization and Schur functions that the optimal data placement is obtained by placing as many of the most popular objects as can fit on one disk and by repeating this process for the remaining objects and disks. These results are generalized for the case of more than one on-line disk drives.

In the case of tape libraries, the tape exchange cost is still significant, but another important cost (which can be the dominant cost when the library stores tapes with very large capacities) is the cost of sequentially searching throughout the tape to find the data that is needed. We separately considered tapes of two rewind technologies: zone and PBOT rewind, since the expected distance searched (and the analysis for its minimization) is different depending on the rewind technology. For each tape technology, the analysis was further specialized depending on whether the implemented scheduling policy of requests is Scan or FCFS. However, the analysis under Scan scheduling has been left out since it produces the same results with FCFS scheduling (it can be found in ([4])).

We showed that when tapes rewind to the nearest zone, the optimal placement must randomly distribute the T highest probabilities in the middle location of each tape, the second and third T highest probabilities to the left and right of the middle location of each tape and continue likewise. For tapes that rewind to the PBOT it is optimal to place the T highest probabilities on the first location of each tape, the second T highest probabilities on the second location of each tape and so on. The

above analysis considered only head positioning cost. The exchange cost was omitted for space reasons and because its effect to the optimal data placement strategy is equivalent to that shown for disk libraries. The analysis for head and exchange cost of the same order of magnitude can be found in ([4]).
